Abstract

Many pathogenic bacteria harbor a type III secretion system to translocate effector proteins from the bacterium into the host cell cytosol. This one-step translocation requires a nanomachinery which was termed injectisome. It consists of a basal body, spanning the two bacterial membranes, and a needle-like structure, bridging the distance between the bacterium and the target cell. Control of the length of the type III secretion injectisome needle is crucial for a correct function.

In *Yersinia*, the YscP protein is involved in needle length control: the number of YscP residues directly correlates with needle length. In this thesis, this correlation was shown to be dependent on the secondary structure of YscP. By substitution of individual residues, needle length could be altered without changing the number of residues in YscP. The molecular ruler model was proposed for length control of the *Yersinia* injectisome needle. There are, however, two possibilities for the molecular ruler model regarding the amount of YscP needed for regulation of the needle length of one injectisome. In the static model, only one molecule of YscP and in a more dynamic model, several proteins are required for length control of one needle. Here, it was demonstrated that partially diploid bacteria, expressing a short and a long YscP simultaneously assemble distinct sets of short and long needles. These results suggest that only one YscP molecule is required for length control of one needle. In *Yersinia*, the YscU protein (a member of the export machinery) was suggested to be involved in the substrate specificity switch. Here, YscU was demonstrated to play a role in substrate recognition but not in substrate switching. Taken together, a refined model for length control of the *Yersinia* injectisome needle is proposed in this thesis, confirming the role of YscP as a molecular ruler.

Introduction

Type III secretion

Type III secretion is a protein export pathway (Figure 1) which is found in many pathogenic or symbiotic bacteria such as *Yersinia spp.*, *Salmonella spp.*, *Pseudomonas aeruginosa*, *Shigella spp.*, the enteropathogenic *Escherichia coli* (EPEC) as well as in plant pathogens like *Erwinia amylovora*, *Mesorhizobium loti* or *Pseudomonas syringae* [1].

The type III secretion pathway is involved in both the assembly of the flagellum and the virulence-associated injectisomes [2]. It enables bacteria to secrete proteins across the inner bacterial membrane, the periplasm and the outer bacterial membrane, independent of the sec-pathway and without a periplasmic intermediate (Figure 1; [3]).

Figure 1

The type III secretion system

Upon contact with the host cell membrane, the tip complex assists with the assembly of the translocation pore, serving as an assembly platform. The effector proteins can now be translocated into the host cell cytosol.

After contact with the target cell *in vivo* [4 - 6] the virulence-associated type III secretion allows bacteria to inject virulence proteins (effectors) across the eukaryotic plasma membrane into the target cell cytosol. The translocated effectors then alter host-cell functions like cytoskeletal architecture, signal transduction or immune response.

Yersinia

The genus *Yersinia* belongs to the group of gram-negative *coccobacillus*-shaped bacteria in the family of *Enterobacteriaceae*. Three species among the genus *Yersinia* are known human pathogens: *Y. pestis*, *Y. pseudotuberculosis* and *Y. enterocolitica*. Although their route of infection differs, they share the ability to reach the lymphoid tissue by a common tropism while avoiding the host's nonspecific immune response and killing by polymorphonuclear neutrophils (PMNs) [7 - 12]. Within the host tissue *Yersinia* proliferate as extracellular pathogens [13 - 15]. *Y. pestis* is transmitted by flea bites, distributed via the blood stream and causes bubonic plague. In contrast, *Y. pseudotuberculosis* and *Y. enterocolitica* are food-borne pathogens, that enter the lymphatic system via M cells of the small intestine upon ingestion [16, 17]. They invade the Payer's patches which are gut-associated lymphoid follicles, and finally reach the mesenteric lymph nodes [18]. *Y. enterocolitica* infections in humans lead to gastrointestinal symptoms like diarrhea or mesenteric lymphadenitis. In addition, *Y. pseudotuberculosis* causes a mesenteric adenitis in humans, mimics appendicitis or induces a septicemia [19 - 21].

The ability to cause infections is dependent on the 70 kb virulence plasmid, called pYV (plasmid involved in *Yersinia* Virulence, [22]) in all three species. The pYV plasmid encodes for the complete type III secretion system and the virulence proteins (effectors), which are injected into the cytosol of the target cell by a nanomachine called injectisome. The virulence proteins, so called Yops (for *Yersinia* outer proteins), are further divided into two groups. The first group consists of translocators which are responsible for the formation of a pore-like structure into the plasma membrane of the target cell. The second group includes effector proteins that are injected through the hypothetical pore into the host cell where they alter several host-cell

functions [23]. Furthermore, the pYV plasmid harbors genes encoding chaperones (Syc; [24]), adhesion proteins (e.g., YadA), an arsenite resistance [25] and proteins involved in regulation and assembly of the injectisome. While the Yop effectors and their chaperones are spread all over the plasmid, the genes encoding the machinery (Yscs, for Yop secretion) and the translocators are clustered in operons.

The *Yersinia* injectisome

The type III secretion system consists of a membrane embedded basal body, spanning the two bacterial membranes and the periplasmic space, and a hollow needle protruding from the bacterial surface into the extracellular space (Figure 2; [26 - 31]). The distinct length of the needle is strictly controlled in order to allow injection of the effectors into the target cell cytosol [32]. In some other pathogens the extracellular structure is replaced by either a pilus (plant pathogens; [33]) or a filament (enteropathogenic *E. coli*, [34 - 36]).

The basal structure is composed of two connected pairs of rings each spanning one bacterial membrane [30, 37, 38]. The outer membrane ring is built by YscC, a member of the secretin superfamily which form pores into outer membranes [39, 40]. In analogy to the flagellum the inner membrane ring is called MS ring. It consists of a periplasmic lipoprotein which is a member of the highly conserved YscJ family and another protein called YscD. The latter one is less conserved among the injectisomes, but its centrally located hydrophobic domain led to the speculation that it is the homolog of PrgH, which is part of the MS ring in *Salmonella typhimurium* [28, 41]. The cytoplasmic ring (C-ring) of the flagellum is built by FliM and FliN. These flagellar proteins share sequence similarities to YscQ, which belongs to a highly conserved protein family of injectisome proteins. Although experimental evidence is missing for injectisomes, YscQ is assumed to build the C-ring linked to the MS-ring. This hypothesis is supported by immunogold experiments, showing the localization of the *Shigella* YscQ homologue Spa33 at the cytoplasmic side of injectisomes [38].

Assembly of the macroscopic structures beyond the cytoplasmic membrane and secretion of effector proteins requires an export apparatus, which is conserved among all type III secretion systems [42]. It is composed of five predicted inner membrane proteins (YscR, YscS, YscT, YscU, YscV), supposedly located within the cylindrical structure of the MS ring. Three additional proteins (YscK, YscL, YscN), predicted to be either cytoplasmic or peripherally associated to the membrane complete the export machinery. YscN is a membrane associated ATPase, a member of the AAA⁺ family [43]. Its essential role might be the detachment of chaperones and

the unfolding of the export substrates [44]. The precise stoichiometry and localization of the export apparatus are still unknown.

The extracellular structure of the *Yersinia* injectisome consists of a hollow tube with an inner diameter of 2 to 3 nm and an outer diameter of about 7 nm. It is built by helical polymerization of about 140 subunits of the YscF protein [26, 45]. At the distal end, the needle structure terminates in a tip structure built by a pentamer of the translocator protein LcrV [45 - 47]. The hydrophilic LcrV is thought to act as assembly platform for the pore [45], which is formed by two other translocators (YopB, YopD) upon cell contact *in vivo*. Both, YopB and YopD, have hydrophobic domains [48] and insert into membranes, but also the third translocator LcrV is necessary for pore formation [49 - 52]. The injectisome needle has a defined length [53], which is necessary to bridge the distance between the bacterium and the target cell [32].

Length control in microorganisms

Length control is a common feature in biology, and it is encountered in many complex biological structures. Length control must be ensured by the organism to allow a proper assembly and functionality. Consequently, a number of mechanisms evolved for structures adopting a narrow size distribution. Most studies focus on length control of linear structures, built by polymerization of single building blocks.

Examples for length control in microorganisms are the bacteriophage tail, the flagellar hook, the type III secretion system injectisome needle, and the lipopolysaccharide (LPS) O-antigen.

The bacteriophage tail

The tail of bacteriophage lambda is a thin flexible tube of 150 nm length consisting of 32 disks [54], each of which is a ring-like hexamer of the major tail subunit gpV [55, 56]. Eleven genes are required for the assembly of the bacteriophage lambda tail (genes Z, U, V, G, T, H, M, L, K, I, and J [57 - 60]) and three models for length determination of the tail were proposed. First, the Cumulative model suggests an increase in deformation of subunits, which polymerize at the growing end of the tail and therefore, ultimately, a blocking of further addition of subunits. Here, tail length is determined by the intrinsic properties of the subunits [61, 62]. Second, in the Vernier model, an internal element supposedly co-measures length by elongation alongside the growing tail. When both macromolecular structures reach the same length, elongation of the tail stops and thereby a binding site for a terminator molecule is created [63]. Finally, in the ruler model the length of the phage tail is determined by a ruler or tape measure protein (TMP) around which the tail subunits polymerize. Here, the length of the tail is in direct correlation to the length of the ruler protein [64]. Mutations in the tail subunit gpV such as deletions or amino acid substitutions do not affect tail length [65], whereas deletions and insertions in the 92-kDa α -helical protein (60% helical content) encoded by gene H (gpH) result in shorter or elongated tails, respectively [66]. Additionally, the tail length is proportional to the amino acid sequence length of gpH mutants [67]. Alterations in the C-terminal part of gpH,

which is needed for initiator assembly [68], do not change the length of the phage tail. These newer findings clearly supported the Ruler model (Figure 3). Polymerization of the tail subunit gpV on the baseplate is initiated by six gpH proteins [56, 69] which attach to the baseplate as a supramolecular assembly *via* their C-termini. During polymerization of gpV around the six gpH molecules, the TMPs supposedly unfold and serve as tape measure and scaffold at the same time [66]. The growing end of the tail is thought to be protected by the N-terminal part of gpH. Once the tail has reached the length of the stretched gpH protein, the continuously growing gpH-unprotected end would be available for the terminator protein gpU. As a result, stopping of the gpV assembly (Figure 3) [70] and cleavage of gpH [71, 72] is initiated. This two-step process includes a molecular ruler controlling the tail length and a growth terminator locking it in the correct length.

Figure 3

Determination of phage tail length in bacteriophage lambda

During polymerization of the tail subunits, the TMPs (gpH) unfold and serve as tape measure and scaffold. The N-terminal parts of the TMPs protect the growing end of the tail from the terminator protein (gpU). The unprotected tail is available for the terminator protein, which stops polymerization of the tail subunits.

A similar mechanism for tail length determination was found for bacteriophage T4 (reviewed in [73]). Although the organization is more complex, the sequence length of TMP gp29 was found to be proportional to the tail length. Furthermore, structure predictions suggested that the stretched 64 kDa protein gp29 would be sufficiently long to act as a molecular ruler [74]. A strain lacking protein gp3 showed the same phenotype as ΔgpU in bacteriophage lambda: a slow and aberrant

elongation of the tail tube, suggesting gp3 as counterpart of gpU acting as a terminator of tail assembly [75]. This hypothesis was validated by showing that gp3 forms a hexameric ring, terminating the tail once it has reached its correct length [76]. In contrast to gpH from bacteriophage lambda, gp29 is supposedly attached to the baseplate via its C-terminus and to the tip of the growing tail via its N-terminus during tail elongation.

Several other studies revealed that TMPs are found in almost all bacteriophages with flexible non-contractile tails, e.g., lambdoid [68] and T phages [73], mycobacteriophages [77] and lactococcal bacteriophages [78]. The length of the TMP proteins are in direct correlation to the corresponding tail length [67, 73]. However, for some phages the TMP is longer than a tail spanning α -helix. This suggests that some regions of these proteins do not participate in length determination [77]. The *tmp* genes are generally encoded on the same locus, though gene length and sequence of TMPs differs even within the same group of bacteriophages [77].

A comparative genomic analysis of 14 mycobacteriophages revealed conserved motifs related to known small proteins which are unrelated to phage or prophage genomes. The role of these motifs is still unclear, suggesting an additional function for TMPs [77]. For mycobacteriophage TM4 it was suggested that the TMP spanning the tail is involved in triggering DNA-injection into bacteria [79]. More recently, the phage T4 TMP containing motif 3 (mt3) was shown to have a peptidoglycan-hydrolyzing activity facilitating efficient infection of stationary phase bacterial cells [80]. A recent study on phage T5 proposes TMP Pb2, besides its role as molecular ruler, sensing the contact to the phage receptor and then triggers the opening of the head-tail connector for peptidoglycan degradation [81]. In this model the TMP acts as molecular ruler, remains attached, and spans the tail. The contact between phage T5 and its receptor then results in a conformational change of the coiled-coil domain (tape measure domain) of the TMP. This conformational change would be the sensor for the opening of the head-tail connector. After DNA release from the capsid, the C-terminus of the TMP supposedly gains access to the bacterial outer membrane. The conformational changes of the TMP finally result in local

degradation of the peptidoglycan and pore formation by fusion of the two bacterial membranes [81].

These findings suggest a general mechanism for length control of the bacteriophage tail by a molecular ruler. This ruler or TMP consists of two domains, one binding the site of tail assembly initiation and a second domain that tracks the growing end of the tail and prevents binding of the growth-terminating protein. When the tail becomes longer than the TMP, the terminator can bind and lock the tail in its correct length. Moreover, the TMPs might have additional functions in the infection process besides their general characteristics of a molecular ruler.

The flagellum

The bacterial flagellum is a highly complex motility organelle with a built in type III secretion machinery [82]. It consists of the basal body spanning the bacterial membranes, the hook junction and the flagellum filament (Figure 2; reviewed in [83 - 85]).

The flagellar basal body consists of three membrane rings (an outer membrane ring (L-ring), a periplasmic ring (P-ring) [86, 87], an integral membrane ring (MS-ring) [87, 88], a rod spanning the periplasmic space [87] and a cytoplasmic ring (C-ring) [89]. The rod is divided into the proximal rod (FlgB, FlgC, FlgF) and a distal rod (FlgG) [87, 90]. The basal body is surrounded by a stator, which consists of multiple copies of an integral membrane structure made of MotA and MotB. The stator is noncovalently attached to the peptidoglycan layer, whereas the rotor consisting of multiple copies of FliG is noncovalently attached to the MS-ring. The stator and the rotor form the flagellar motor, which is responsible for torque generation (reviewed in [85]). The flagellar base also incorporates the type III secretion system which is used to export flagellar proteins during flagellar assembly (reviewed in [84, 91]).

An export apparatus, mounted within the cytoplasmic side of the MS-ring, translocates most external proteins of the flagellum to their site of assembly through a narrow channel of the structure [92 - 94]. It is a multi-protein complex, structurally and evolutionarily related to the virulence associated type III secretion system [27, 91, 95], and it is composed of six membrane proteins (FlhA, FlhB, FliO, FliP, FliQ, FliR)

and three soluble proteins (FliI, FliH, FliJ) [95]. The ATPase complex consisting of FliI (ATPase), FliH, and the chaperone FliJ, is thought to deliver the substrates for the export [96].

The flagellum filament is a long and cylindrical structure of helical shape. The filament is of variable length (5-10 μm), but has a constant diameter of ~ 20 nm. The major subunit of the filament is FliC (flagellin). In contrast to the hook cap, the filament capping protein FliD, which enables flagellin subunits to polymerize at the distal end, remains attached [97 - 99].

The hook is a cylindrical hollow structure serving as a joint between the basal body and the filament. It consists of ~ 130 subunits of FlgE [87]. Assembly of the flagellar hook depends on the hook capping protein FlgD which acts as a scaffold [100 - 102]. Control of hook length was postulated to be essential for proper function and behavior of the cell. The distinct hook length was found to be 55 ± 6 nm [103] which is necessary to generate a sufficient bend angle for efficient transmission of the torque [104, 105]. To date several theories have been proposed to explain the mechanism how hook length is controlled.

The *fliK* gene was the first gene identified as a regulator of hook length in a broad screen of mutants [106]. The $\Delta fliK$ mutants were non-motile with hooks of uncontrolled length (ranging from 40 – 900 nm) and no filament attached. The described phenotype was named superhooks [106] later renamed polyhooks [103]. The failure to terminate the hook at its proper length and to initiate filament assembly in $\Delta fliK$ mutants suggested that FliK is a bi-functional protein [105].

Indeed sequence analysis of the 405 amino acid long protein [104, 107] revealed at least three functional regions: a moderately conserved N-terminus (FliK_N, residues 1-180), a proline-rich central part serving as linker (FliK_L, residues 181-205) and a highly conserved C-terminal region rich in glutamine residues (residues 206-405), which is thought to be of high conformational flexibility [104, 108]. The C-terminal region consists of a highly stable, compactly folded region (residues 206-370 FliK_C) and a partially unfolded stretch from residue 371-405 (FliK_{CT}) [109]. Residues 265 to 405 are particularly involved in the switching process, as shown by mutagenesis analysis [109]. The identified domain is highly conserved among the

YscP/FliK family [110] and was therefore named T3S4 (Type Three Secretion Substrate Specificity Switch) in FliK [107] and YscP [110].

Furthermore, full length FliK is exported into the culture medium by the flagellum type III secretion pathway. The N-terminal first 40 amino acids seem essential for export of FliK [111]. Export of FliK is important for termination of hook elongation and initiation of filament formation and thus is part of the switch [109]. It should be noted, that some N-terminally truncated FliK variants were not secreted but still switched substrate specificity [112]. However, their switching ability was dependent on their expression level [112]. Therefore, the role of the N-terminus of FliK remains unclear. Moreover, FliK secretion was reported to be independent from hook length control [113].

Many pseudorevertants showing a polyhook-filament phenotype [104, 105, 114] were observed and extragenic suppressor mutations were always mapped in *flhB* [103, 115]. The majority of mutations lay towards the 3' end of *flhB*, leading to a disruption of the predicted cytoplasmic domain of the integral membrane component of the export apparatus [105]. FlhB was reported to be involved in the substrate specificity switch by an autoproteolytic cleavage [116]. It was proposed that FliK measures hook length and senses it to FlhB to switch the export substrate specificity [105].

Observations that mutations leading to short hooks were not within the *fliK* gene (as it would be expected in the case of a molecular ruler mechanism) but mapped in *fliM*, *fliG* or *fliN*, encoding for three proteins that form the so-called C-ring beneath the basal body led to another model for length control. The measuring cup model [117] (Figure 4) proposes that the C-ring forms some kind of a cup providing binding sites for all hook subunits (FlgE) and thereby controlling hook length. Upon clearance of the measuring cup, the export machinery is accessible for a switching protein resulting in export of the filament subunits.

In this model, hook length is not determined by FliK but by the number of FlgE proteins fitting into the cup. However, FliK is necessary to switch substrate specificity and finally terminate hook elongation. Interestingly, in $\Delta flgD$ mutants (hook cap) the hook subunits do not assemble on the rod. Furthermore, the hook subunits are

secreted, but the substrate specificity switch by FliK does not take place [100]. Additionally, the model can not explain a lack of a severe effect in case of overproduction of hook subunits [108, 118]. Moreover, as described by Chevance & Hughes [119], the C-ring cup has only room for max. 50 subunits of FlgE [119, 120]. In this calculation, the space required for the ATPase complex FliH/J is not considered, and it is unknown if FlgE has associated chaperones. Thus, for a functional cup model, the cup must for example fill and empty 4 times with 30 subunits in order to produce a 120-subunit-long hook. This suggests a more complicated mechanism and imposes a higher complexity for the C-ring than a simple measuring cup device to control hook length [119]. Nevertheless, it should be noted that overproduction of FlgE increases the frequency of polyhook phenotype [118].

Figure 4

The cup model [117]: The C ring of the basal body is filled with hook subunits (1); the subunits are exported and the hook elongates (2); FliK switches the substrate specificity (3); flagellin is exported and the filament grows (4).

Reprinted by permission from Macmillan Publishers Ltd: *Nature Reviews Microbiology* (Cornelis, 2006, *Nature Reviews Microbiology* **4**, 811–825) ©2006

A further model for hook length control was proposed by Moriya *et al.* [118]. In the molecular clock model [118], a dual hook-length control mechanism is proposed, dependent on the rate of hook elongation and on an intrinsic timing device. This timing device either programs the export machinery to switch substrate specificity or slows down the export of hook subunits, independent of hook length. Nevertheless, a complete switch to export filament subunits still depends on an infrequent ruler protein or a tape measure protein [118]. Evidence for the molecular clock model is based on the following observations: *flgE* mutants are defective in polymerization and therefore hook growth rate is slowed down and the timing device stops elongation earlier which results in shorter hooks compared to wild type. Over-expression of the FlgE mutants restores growth to wild type level, supposedly due to an increased polymerization rate. Over-expression of wild type FlgE leads to elongated hooks with a broader length distribution likely due to a increased polymerization rate and decreased interaction between FliK and FlhB [118]. Finally, this model accounts for the observed small peak of normal hook length distribution in a knock-out *fliK* mutant ([121]; although there is a broad distribution): the timing device always switches substrate specificity after a fixed time, based on the average from initiation of hook polymerization. Auto-cleavage of the FlhB C-terminal domain [116] was suggested to be the timing device, the molecular clock. The cleavage slows down hook subunit export before FliK_{T3S4} and FlhB_C interact and the resulting conformational change in FlhB leads to the switch [118].

Interactions between FliK_N and the cytoplasmic domain of FlhB (FlhB_C), were reported [109, 116]. Subsequently, it was suggested that FliK_N, recognized as export substrate, senses the hook length reaching its mature length to FliK_C, which leads to structural conformational changes in FlhB_C [109]. In addition, interactions between FliK_N and the hook capping protein FlgD (high affinity), and the hook subunit FlgE (low affinity) were demonstrated [118] supporting the hypothesis that the N-terminus directly monitors hook length and is required for an effective FliK_C and FlhB_C interaction to switch the substrate specificity.

An appropriate frequency of FliK export is necessary to explain the effect of cellular FliK concentrations on hook length. Overproduction of FliK increases the

chance of FliK_{T3S4}-FlhB_C at a slightly earlier timing and therefore shortens hook length, while the decrease of FliK levels also decreases the probability of FliK measuring the growing hook, leading to polyhooks and polyhook filaments [108, 118]. Subsequently, FliK was thought to act as a flexible ruler, a 'molecular tape measure' [118]. Insertion and deletions within the FliK ruler should therefore result in longer and shorter hooks, respectively. Appropriate results were obtained for FliK, but the majority of the deletions led to a loss of function phenotype [113]. This suggests that length control of the flagellar hook does not involve a conventional molecular ruler like for the phage tail. However, most of the deletions in FliK_N result in polyhooks [113] and hence impair the ruler function of FliK. It should be noted that three FliK deletion variants producing shorter hooks were neither detected in culture supernatant nor in the cytoplasm [113]. Therefore, Shibata's conclusion of FliK as the internal ruler and the fact that its secretion is not required for the export specificity switch is not conclusive [113]. In contrast, Minamino *et al.* [122] found that the interaction of FliK_N with the hook and the hook cap is important for an efficient switching process, suggesting that FliK measures hook length inside the hook during the process of FliK secretion.

Hook and filament assembly is a well studied field, but the exact mechanism how FliK measures and controls hook length needs further investigation.

Type III secretion injectisome

The injectisome needle has a defined length of ~ 60 nm for the *Yersinia enterocolitica* Ysc injectisome [53], ~ 30-50 nm for the *Salmonella enterica* type III secretion system [41, 123] and ~ 45 nm for the *Shigella* needle complex [31]. The flagellar hook must be of certain length for mechanical function [104, 105], whereas needle length is optimized to bridge the distance between bacterium and target cell [32]. For length control of the injectisome needle, several hypotheses have been proposed.

The needle length of the type III secretion injectisome is genetically determined as shown for the bacteriophage tail and the flagellar hook. Knock out mutation of *spa32* in *Shigella* [124], *invJ* in *Salmonella enterica* (*Salmonella* pathogenicity island 1, SPI-1) [28] and of *yscP* in *Yersinia* [53] lead to needles of undefined length and loss of

effector export. This phenotype evokes the one described for *fliK* knock out mutants in the flagellum (polyhook structures and no export of filament subunits) [105].

YscP a molecular ruler?

The YscP protein is an early substrate of the injectisome [125]. It is exported by the type III secretion machinery into the culture supernatant, also under non-permissive conditions (high calcium concentrations) for effector release. Under such conditions it is loosely attached to the bacterial surface [125]. YscP harbors two independent secretion signals in the N-terminal region [126] (S1: residues 1-35, S2: residues 97-137), and both differ from the export signals of the effector proteins (Figure 5). The two signals, S1 and S2, seem to be redundant for the secretion of YscP, but both are needed for tight length control of the injectisome needle [126]. This observation was also made for InvJ and FliK. It was shown that secretion of InvJ is essential for length control [127], and that export of FliK during hook assembly seems to be important for length determination [111]. Nevertheless, the export of YscP is not required for switching substrate specificity [126]. However, the secretion signals of both proteins are different from those of YscP [111, 127].

Furthermore, an extragenic suppressor mutation in the *flhB* homolog *yscU* is also capable to restore effector secretion [128]. YscU also undergoes autoproteolytic cleavage as observed for FlhB [129]. Thus, it is likely that YscP and its orthologs fulfil a similar switch function as FliK. This function was assigned to residues 405-500 of the 515 residues YscP [110]. This domain is predicted to have a globular structure, an original α/β fold, a proline-x-leucine-glycine signature and no catalytic activity. Despite limited sequence similarity, the predicted structure is well conserved among the C-terminal region of length-measuring proteins in many injectisomes as well as in the flagellum. Representing a new protein domain, it is called type III secretion substrate specificity switch domain (T3S4) [110].

Deletions of amino acids between residues 36-96 and 222-306 and insertions of additional amino acids between residues 49-50 revealed shorter and longer needles, respectively. Furthermore, a linear relationship for needle length *versus* number of YscP residues was observed. In addition to S1 and S2 of YscP which link

export of YscP with length determination, and the T3S4 domain, two other regions were assigned as ruler regions involved in length control. One builds the spacer between S1 and S2 (residues 36-96) and the other extends from S2 to the T3S4 domain (residues 138-381) [53].

Figure 5

Schematic representation of YscP showing the export signal(s) localized in the amino-terminal part of the protein, and the T3S4 domain localized in the carboxy-terminal part of the protein. A repeat region is localized in the central ruler domain.

The molecular ruler model for YscP is based on the previous findings. According to this hypothesis, length control involves a two-step process: measurement of needle length and switching of substrate specificity. However, two possible explanations were proposed [52, 131].

The initial model is static and proposes that one molecule of the ruler is anchored by its N-terminus to the growing end of the needle and gradually stretches while the needle elongates. In the fully elongated state, the ruler senses the stretch to the T3S4 domain, located inside the basal body, resulting in a switch in substrate specificity. Here, the ruler occupies the channel in an extended form, while the needle subunits simultaneously travel through the channel to the growing end (Figure 6) [53].

Figure 6

The ruler model [53]

YscP enters the channel after completion of the basal structure (1); the needle subunits are exported and polymerize, leading to the extension of the ruler component of YscP (2); the needle assembly is completed (3); the T3S4 domain of YscP switches the substrate specificity to effector secretion and the ruler is released (4).

Reprinted by permission from Macmillan Publishers Ltd: *Nature Reviews Microbiology* (Cornelis, 2006, *Nature Reviews Microbiology* **4**, 811–825) ©2006

The inner diameter of the needle is only 2-3 nm, raising the question whether the ruler and the needle subunit could occupy the channel simultaneously. A few elements do not perfectly fit with this ruler model. Indeed, it was shown that over-expression of YscP can improve length control [126, 130]. Consequently, a more dynamic version of the ruler model was proposed (Figure 7a; [131]). Here, the needle length is monitored by more than one ruler, which is exported in alternation with the needle subunit. And as proposed for FliK [118] the ruler can only switch substrate specificity, when the needle structure reaches the correct length (Figure 7a).

Figure 7

Alternative models for needle length control

a | The dynamic ruler model [131]: Here, ruler and needle subunit molecules are exported alternately (1 to 4). The ruler checks the length while traveling through the channel (1 and 3). When the exact length is reached, the ruler switches the substrate specificity (5), leaving the injectisome ready for translocator and effector protein (Yop) export (6). b | The inner rod model [123]: Needle length control by timing of substrate switching. In this model, InvJ stabilizes the socket substructure (shown in red (1)), which is necessary for the assembly of the inner rod (black subunits composed of PrgJ). Note that the needle (white subunits, composed of PrgI) assembles simultaneously (2, 3). Termination of the inner rod results in conformational changes that lead to substrate switching (4). Late substrates are then exported (5).

So far, a correlation between needle length and length of the ruler protein is known only for the *Y. enterocolitica* injectisome [53]. For the *Shigella* injectisome needle it was suggested that Spa32, an YscP homolog, acts rather as a tape measure protein than as a molecular ruler [132]. The molecular ruler is suggested to

stretch during needle growth, whereas the tape measure protein is secreted during needle elongation. Finally, investigation of the *Salmonella* SPI-1 injectisome led to another hypothesis. Marlovits *et al.* [123] proposed for *Salmonella enterica* (SPI-1) that assembly of the inner rod determines the length of the type III secretion injectisome needle. The 'Inner Rod model' suggests for InvJ, a counterpart of YscP, a new function in respect of length control. In *invJ* knockout mutants a socket like structure, acting as linker between the inner rod and the base of the basal body, is missing and the needles easily break off. InvJ is proposed to stabilize the socket and thus allows proper assembly and anchoring of the rod and the needle. In a previous study, Marlovits *et al.* [37] showed significant conformational changes on the cytoplasmic face of the basal body upon completion of the injectisome. These changes were suggested as structural basis for the substrate specificity switch. It was suggested that a properly anchored rod is necessary for switching the substrate specificity (Figure 7b).

Many questions on the mechanism have been addressed and there is given evidence for the ruler model as the appropriate one for the *Y. enterocolitica* injectisome needle. However, experimental evidence for one or the other molecular ruler model is still lacking.

The O-antigen of the lipopolysaccharide

Another example of length control in microorganisms exists for the O-antigen chain of the lipopolysaccharide (LPS). LPS represents the major surface structure of Gram-negative bacteria and consists of a polysaccharide O-antigen chain, a core oligosaccharide and lipid A which anchors the LPS molecule in the outer membrane (reviewed in [133]). LPS isolated from exponentially growing bacteria is heterogeneous in size, as seen by characteristic ladder patterns in gel electrophoresis [134 - 136]. Although the size of the O-antigen varies to a certain extend, there is a characteristic strain-specific modal chain length. In general, O-antigens are assembled by the so-called Wzy-dependent pathway (reviewed in [137]), where the O-antigen is synthesized on a polyisoprenoid lipid carrier at the cytoplasmic side of the inner membrane. The intermediates are then translocated

across the inner membrane with the help of the integral membrane protein Wzx. These lipid-linked oligosaccharides are polymerized en bloc in a periplasmic reaction, involving the integral membrane protein Wzy. In the final stage of LPS biosynthesis the O-antigen is linked to a preformed lipid A-core molecule prior to surface translocation of the completed molecule.

The integral inner membrane protein Wzz determines the O-antigen chain length [138, 139] and is a homolog to the polysaccharide co-polymerase (PCP) protein (class 1). These proteins have a regulatory role in polymerization [140, 141]. PCP family members (including families PCP-1, PCP-2, and PCP-3) share a conserved membrane topology. They consist of two transmembrane (TM) helices that flank a large hydrophilic periplasmic domain (PD), which contains amino acid sequences predicted to form coiled-coils (CCs) and which possesses a proline-rich consensus motif at the C-terminal TM span (TM2) [142 - 146].

The SDS-PAGE profiles of LPS isolated from wzz-null mutants are non-modal, where polymerization is terminated prematurely and a random distribution of O-antigen chain length, favoring a low number of repeat units in the polysaccharide, is observed. In complementation experiments, expression of heterologous wzz genes in a wzz-deficient background results in O-antigens with chain lengths characteristic for the source of the wzz gene [139, 143, 147, 148].

The mode of action of these proteins, however, remains obscure but two possible regulatory strategies have been postulated: a 'molecular stopwatch' [143] and a 'molecular ruler' [144]. To obtain insight into the Wzz mechanism, crystal structures were obtained for the periplasmic domains of three Wzz homologs (WzzPD) [149]. In each case, the domain forms an extended α -helical hairpin connected to an α/β base domain. The protomers assemble into complexes containing three, five, eight, or nine subunits (depending on the particular Wzz homolog) [149]. From these structural studies it was proposed that the oligomerization state of Wzz homologs defines the molecular ruler responsible for determining O-antigen chain length [149]. However, Larue *et al.* [150] studied various full-length Wzz homologs and observed different oligomeric states compared to those of the periplasmic domains alone [149, 151]. In case of a reconstitution in a

lipid bilayer, the full-length Wzz homologs all display the same quaternary structure, which contradicts the molecular ruler hypothesis.

Nilsson *et al.* [152] showed that *Helicobacter pylori* varies its LPS fucosylation pattern and that alteration of the number of heptad repeats in the fucosyltransferase sequence results in a corresponding size change of the glycosylated O-antigen chain. They demonstrated that one heptad repeat in the fucosyltransferase corresponds to one *N*-acetyl-lactosamine unit in the O-antigen polysaccharide, which supports the molecular ruler model [152].

Substrate specificity switch

YscU/FlhB

Mutations affecting FlhK, the flagellar YscP homolog, lead to extra-long hooks (called polyhooks) but no filament and hence bacteria are not motile [103]. Motile revertants appear as a consequence of extragenic suppressive mutations in the integral membrane protein FlhB, suggesting a role for FlhB in specificity switching [105, 115]. FlhB has a long C-terminal cytosolic domain, which undergoes an autoproteolytic cleavage between N269 and P270; the resulting subdomains however, remain tightly associated with each other [116, 153, 154]. This cleavage is abolished by the mutation N269A and cells producing FlhB_{N269A} assemble polyhook structures lacking filaments. It was proposed that cleavage and interaction of the two fragments generates conformational changes important for the specificity switching process (reviewed by [155]).

Figure 8

The FlhB homolog in the *Yersinia* injectisome is called YscU, a 354-residue polypeptide with four transmembrane helices and a long cytoplasmic tail [156]. As observed for FlhB, YscU undergoes autoproteolytic cleavage before P264,

generating a 10-kDa C-terminal fragment [129]. YscUN263A is resistant to this cleavage, but interestingly retains the capacity to secrete Yops [129].

The position of LcrV at the tip of the needle implies that LcrV is exported immediately after YscF but before the Yops. Thus, the hierarchy of secretion must consist of at least three categories of substrates and not only two as in the flagellum. There are, however, no genetic data to support this assumption.

Aim of the Thesis

The aim of this PhD thesis is to understand the mechanism of needle length control in the *Yersinia* injectisome. It was previously shown that the number of residues of the protein YscP correlates to the length of the injectisome needle, suggesting that YscP might act as a molecular ruler determining the needle length. Moreover, YscP has two N-terminal secretion signals and it was demonstrated that YscP itself needs to be exported to fulfill its function. In addition to length determination of the injectisome needle, YscP was shown to be required to switch on the export of late substrates. This function was assigned to the C-terminal domain, called substrate specificity switch domain (T3S4). However, the exact mechanism and the interacting partners still remain unclear. The protein FlhB, a homolog of YscU and a transmembrane protein in the flagellum was shown to be involved in this switching. Therefore, the role of the FlhB homolog in *Yersinia* (YscU) was investigated.

The original ruler model suggested that YscP and the needle subunit YscF travel at the same time inside the growing needle. However, some data suggest a more dynamic model, where several YscP molecules are released alternating with YscF proteins.

Therefore, the main questions addressed in this thesis are the following:

1. How does YscP measure the length of the injectisome needle - what is the role of the ruler domains?
2. How many YscP proteins are needed to control the length of a single needle?
3. What is the role of YscU in needle length control and substrate specificity switching?
4. Does YscP act as a molecular ruler or as a timer?
5. Which other proteins are involved in needle length control?

Results

How does YscP measure the length of the injectisome needle?

What is the role of the ruler domains?

The helical content of the YscP molecular ruler determines the length of the *Yersinia* injectisome

Summary

The length of the *Yersinia* injectisome needle is determined by the protein YscP, which could act as a molecular ruler. The analysis of the correlation between the size of YscP and the needle length in seven wild-type strains of *Yersinia enterocolitica* reinforced this hypothesis but hinted that the secondary structure of YscP might influence needle length. Hence, 11 variants of YscP₅₁₅ were generated by multiple Pro or Gly substitutions. The needle length changed in inverse function of the helical content, indicating that not only the number of residues but also their structure controls length. Taking the secondary motifs into account, Pro/Gly-variants were subjected to *in silico* modelling to simulate the extension of YscP upon needle growth. The calculated lengths when the helical content is preserved correlated strikingly with the measured needle length, with a constant difference of ~29 nm, which corresponds approximately to the size of the basal body. These data support the ruler model and show that the functional ruler has a helical structure.

Introduction

Size determination represents a fundamental problem for multi-component biological structures with a complex architecture including tubular components (Marshall, 2004). In few cases, like the tail of bacteriophages, it appears that one protein acts as a tape measure or a molecular ruler (Katsura and Hendrix, 1984; Katsura, 1987; Pedulla *et al.*, 2003). The molecular ruler, in its

elongated state, determines the number of subunits of another protein that are allowed to polymerize to create the tubular structure. The same concept has been proposed to determine the length of the needle of the bacterial injectisome (Journet *et al.*, 2003) and of the flagellar hook (Moriya *et al.*, 2006). In the latter cases, the situation is more complex than in bacteriophages because the needle and hook are assembled outside from the bacterial cytosol and the exact mechanism remains a matter of debate. The flagellar hook-length control and assembly have been recently comprehensively reviewed (Waters *et al.*, 2007; Chevance and Hughes, 2008).

The injectisome or needle complex allows pathogenic or symbiotic bacteria to inject effector proteins across eukaryotic cell membranes, a process called type III secretion (T3S). This nanomachine, which is evolutionary related to the flagellum (Macnab, 2003), consists of a basal body surmounted by a hollow stiff needle (Kubori *et al.*, 1998; 2000; Blocker *et al.*, 1999; 2001; Hoiczyk and Blobel, 2001), a filament (Knutton *et al.*, 1998; Daniell *et al.*, 2001; Crepin *et al.*, 2005) or a pilus (Van Gijsegem *et al.*, 2000) that projects from the bacterial surface into the exterior milieu. The basal body is made of several rings embedded in the two bacterial membranes (Blocker *et al.*, 1999; 2001; Marlovits *et al.*, 2004; Morita-Ishihara *et al.*, 2006). The MS ring, spanning the plasma membrane, contains a number of integral membrane proteins constituting the core of the T3S export apparatus (reviewed by Tampakaki *et al.*, 2004; Cornelis, 2006; Galan and Wolf-Watz, 2006; Yip and Strynadka, 2006).

The *Yersinia enterocolitica* Ysc injectisome terminates with a 65-nm-long stiff hollow needle, made of ~140 copies of the 9 kDa YscF protein (Hoiczyk and Blobel, 2001). At the tip of the needle, a pentamer of LcrV (Mueller *et al.*, 2005; Broz *et al.*, 2007) forms a tip structure serving as an assembly platform for the translocation pore (Goure *et al.*, 2005; Mueller *et al.*, 2008). In *Y. enterocolitica*, the needle detaches very easily from the bacterium and the detached needles have a constant length, implying that they detach from their origin or brake always at the same point (Journet *et al.*, 2003). During morphogenesis, the needle components, like the hook and the filament of the flagellum are sequentially exported by the T3S apparatus itself (Sukhan *et al.*, 2001), travelling through the growing structure and polymerizing at its

distal end (Li *et al.*, 2002; Macnab, 2003). There is no clear hierarchy in the synthesis of the injectisome components and substrates. Thus, the export apparatus is expected to switch its substrate specificity over time so that needle subunits (early substrates) are exported before LcrV (intermediate substrate) and the effectors (late substrates). This substrate specificity switch presumably leads to the arrest of needle growth (Ferris and Minamino, 2006).

The switch to export late substrates is triggered by a protein, which is itself exported, FliK for the flagellum (Hirano *et al.*, 1994; Minamino *et al.*, 1999; 2004) and YscP for the *Yersinia* spp. injectisome. More precisely, this switch function was assigned to residues 405–500 of the 515-residue YscP (Agrain *et al.*, 2005a). This domain, predicted to have a globular structure, an original α/β fold, a P-x-LG signature and no catalytic activity, is called T3S4 for Type 3 Secretion Substrate Specificity Switch (Agrain *et al.*, 2005a). The T3S4 domain is thought to interact with YscU (FlhB in the flagellum), a component of the basal body that is also involved in setting the hierarchy of export (Hirano *et al.*, 1994; Sorg *et al.*, 2007). Overexpression of the T3S4 domain alone allows the system to switch on the export of late substrates but it does not lead to needle length control, implying that the N-terminus of YscP is necessary to determine at which stage the switch has to occur (Agrain *et al.*, 2005b). YscP is itself an early substrate of the machine (Stainier *et al.*, 2000; Riordan *et al.*, 2008) driven by two independent export signals (S1: residues 1–35 and S2: 97–137) and export is required to ensure a proper length control (Agrain *et al.*, 2005b). Deletions between residues 36–96 and 222–306 of YscP and insertions between residues 49 and 50 lead to shorter and longer needles, respectively, with a linear correlation between the size of YscP and the needle length (Journet *et al.*, 2003). This led to a model where YscP acts as a molecular ruler measuring the needle (Journet *et al.*, 2003). According to the model, export of needle subunit proteins would be allowed until the length of the needle reaches the length of the extended YscP ruler domain after which, the T3S4 domain of YscP would signal the secretion apparatus to stop exporting needle subunits. YscP is thus a protein with a dual function, ruler and substrate specificity switch. A similar correlation was observed between the size of FliK and the length of the hook but it was interpreted in a different way (Shibata *et al.*, 2007).

In this paper, we provide evidence that not only the number of residues but also the secondary structure of YscP plays a role in determining the needle length and we show that the predicted length of various YscP variants in their functional state approximates to the actual needle length that they determine. These data further support the ruler model (Journet *et al.*, 2003).

Results

The needle length is not constant in the Y. enterocolitica species

The needles made by *Y. enterocolitica* E40 endowed with YscP from *Yersinia pestis* KIM are shorter than the natural needles of *Y. enterocolitica* E40 (Journet *et al.*, 2003). This observation indicates that the needle length varies within the genus *Yersinia* and suggests that it might vary also within the species *Y. enterocolitica*. As this information might be valuable for the understanding of the mechanism, we sequenced the *yscP* genes in seven isolates belonging to different serotypes and biotypes of *Y. enterocolitica* (Table S1). The sequences (aligned in Fig. S1) revealed that the YscP proteins varied from one another by the number of times three different motifs are repeated (Fig. 1A). The shorter protein had only 453 residues while the longer one had 551 residues. We then measured the needles made by all these strains (Fig. S2) and, as expected, the plot of the needle length versus the number of residues of YscP (Fig. 1B) indicated a linear correlation. Interestingly, however, for two strains, the point was clearly off the regression line. In particular, needles from strain IP17, having the longest YscP (551 aa), were significantly shorter than the needles from WAT9/88, which has a 539-aa YscP. In addition, three strains, which have an YscP protein of 515 aa, did not synthesize needles of exactly the same length. All this suggested not only that the length of YscP was determining the needle length but that, possibly, another parameter could be involved. Comparing the different YscP sequences, it appeared that there were variations in the percentage of proline residues and in the content of predicted α -helices (Fig. 1A).

The needle length correlates with the helical content of the ruler part of YscP

To test the hypothesis that the helical content of YscP may influence the needle length, we turned to YscP from strain W22703, the model protein which was used in our previous work (Journet *et al.*, 2003). We first substituted four, six or eight prolines that occurred within predicted unstructured regions (Pro 174, 181, 185, 188, 237, 238, 244, 252) by alanines, which are strong helix formers (Chou and Fasman, 1978) and we replaced four, six or eight residues in the middle of putative predicted α -helices by prolines (Gln 212, 217; Leu 268, 283, 303; Glu 277, 375, 379), as schematized in Fig. 2A. The eight recombinant YscP proteins had thus the exact same number of residues as wild-type YscP (515 aa), but they determined different needle lengths (Fig. 2B and C). Although the median lengths did not differ from more than 15 nm, the differences were statistically significant and

Fig. 1. Correlation between the YscP number of residues and the length of needles present in various different wild-type strains. A. Schematic representation of the sequences of the different YscP proteins. The proteins differ by the number of repetitions of three sequences. B. The needle length plotted against the total number of residues in YscP.

there was a linear correlation between the number of prolines in YscP and needle length (Fig. 3 lower slope). As a control, four residues in non-helical regions were also substituted by prolines (Glu 145, 151; Leu 162; Gln 165) (pSTW44) (Fig. 2B) and, in this case, substitutions did not affect the needle length (66 nm versus 65 nm for the wild type).

This result suggested that the impact of prolines might be due to the breakage of α -helices. To test this hypothesis, four residues in predicted helices (Gln 212, 217; Glu 375, 379) were substituted by glycines (pSTW46), known to be as strong helix breakers as prolines (Chou and Fasman, 1978). Here again, the substitutions had impact on needle length, which increased to 70 nm (Figs 2B and 3), suggesting that indeed the helical content of YscP within the 138–380 domain as predicted by bioinformatics tools is highly correlated with the needle length (Fig. S3). *A posteriori*, these mutagenesis results also concur to validate the initial prediction of the secondary structure for YscP protein (see *Experimental procedures*).

The length of the extended YscP is consistent with the needle length

The data presented so far suggest that the functional conformation of YscP includes α -helices. We thus tried to have an insight into the actual length of YscP in this conformation. In order to do this, an *in silico* molecular dynamics (MD) approach was used to simulate the pulling of the protein starting from a random initial conformation, which would mimic the extension of YscP upon needle growth (see *Experimental procedures*). We modelled the secondary structure of region 36–380 of YscP. This includes (i) the region between signal 1 and signal 2 (36–96) that remains invariant in the present set of simulations, (ii) signal 2, and (iii) the central ruler region (138–380), affected in the present set of YscP mutants. We submitted the wild type along with nine variants (Table S2) to a series of independent steered MD simulations both in water and *in vacuo* (see *Experimental procedures*). From the analysis of YscP extension under constant velocity

Fig. 2. Effect of amino acid substitutions in YscP on the heptide length.

A. Schematic representation of YscP. Secondary structure predicted by SIMP-A36. Blue bars = α helices; red bars = β sheets; purple bars = unstructured. B. Table showing the substitutions introduced between residues 138 and 380. Note that prolines have been removed from unstructured domains (except for position 303) while they were inserted into predicted α -helices, except for plasmid pSTW44 where the substitutions have been made in a region predicted to be unstructured (control). Glycines were also introduced into predicted α -helices.

C. The histograms of length measurements. s.d., standard deviation; n , number of measured needles.

Fig. 3. Molecular modelling of YscP protein and comparison with experimental needle length. Computed lengths of the YscP_{36–380} wild type and mutants are reported in circles (top), and are compared with the experimental measures of the needle (in triangles at the bottom). The computed YscP_{36–380} lengths result from a series of ~20 independent steered MD trajectories for each protein; results from explicit solvent MD simulations are also reported (empty squares at the bottom). The distance between residues 36 and 380 has been measured when 90% of the helical content is conserved. Correlation between needle length and number of prolines substitutions is shown in the lower slope (triangles). Note that all the measurements align along a straight line except for pSTW44. All the values were compared with the wild-type value by the *t*-test. The stars indicate the probability of difference to wild type. NS = *P* > 0.05 (not significant). *0.05 > *P* > 0.01 (significant). **0.01 > *P* > 0.001 (very significant). ****P* < 0.001 (extremely significant).

pulling, we found that the helical regions are conserved within the ns timescale, and upon pulling YscP models extend maintaining their initial secondary structure. As far as YscP approaches a fully linear extended conformation, α -helices abruptly start to break under mechanical stress, eventually reaching a completely extended β -strand-like conformation. The length values observed in MD simulations before the unfolding of any α -helix within region 36–380 of YscP (using a confidence threshold set to 90% of the initial helical content, see *Experimental procedures*) are plotted against the relative number of prolines in Fig. 3 (upper slope). We interestingly found that when the initial helical content of YscP_{36–380} is preserved, the length of the wild-type protein (93.5 nm) along with the mutant conformations is strikingly correlated with the measured needle length, showing a constant difference of ~29 nm between the length of YscP and the length of the needle (Fig. S4). This value corresponds approximately to the distance between the cytoplasm and the surface of the basal body (26 nm) (Blocker *et al.*, 2001; Marlovits *et al.*, 2004). Hence, YscP is properly commensurate to the length of the injectisome from the inner side of the plasma membrane to the needle tip. Given the T3S4 domain of YscP is supposed to interact with the cytosolic domain of the transmembrane protein YscU, these data provide strong grounds to the ruler hypothesis.

In *Y. enterocolitica* needles are very fragile, to the extent that, even in electron microscopy analyses from non-sheared cultures, most needles appear to be detached from the bacterium. These detached needles have a constant length as shown here and in our previous work (Journet *et al.*, 2003; Agrain *et al.*, 2005a,b; Sorg

et al., 2007), implying that they always break at the same point. To validate our interpretation of the length measurement data, we had to ensure that detached needles have the same length as attached needles measured from the bacterial surface, in other words, that needles break at the bacterial surface. We checked this on wild-type bacteria and we measured on the same preparations 63 attached needles where the insertion point was clearly visible and 100 detached needles. As shown in Fig. 4, the length was similar (66 ± 8 nm and 65 ± 7 nm respectively), showing that indeed our interpretation of the length, supporting the ruler model, was correct.

The width of YscP is compatible with the needle channel size

The molecular modelling analysis thus confirms that the functional form of YscP consists in a succession of α -helices that modulates the needle length. The model of the molecular ruler, as presented earlier (Journet *et al.*, 2003), proposes that the ruler is located inside the growing needle. Based on the hypothesis that YscP is fully extended conserving its helical content, the width of the wild-type ruler was evaluated using our computational models for YscP. For every residue *i*, the protein's width was calculated by measuring the minimum and maximum size of the smallest box including all the atoms in residues window [*i* − *n*, *i* + *n*], when the modelled YscP is fully extended (the graph in Fig. 5 shows the results for *n* = 5). The average min–max width of the ruler goes from 0.79 ± 0.10 nm to 0.95 ± 0.10 nm, and it never reaches values higher than 1.3 nm. Given that the needle is known

Fig. 4. Length of attached and detached needles. Left: Electron micrographs showing attached and detached needles. Right: Histograms showing the needle length N , number of measured needles; s.d., standard deviation.

from cryo-electron microscopy experiments to have a section of 2–3 nm (Blocker *et al.*, 2001; Mueller *et al.*, 2005), the YscP protein can be easily accommodated within the needle cavity, although presenting conserved helical motifs. Moreover, on the needle channel there

would be enough space to accommodate at the same time both the YscP protein and the YscF building blocks of the needle. Based on this structural analysis, non-specific interactions between YscP and YscF proteins can likely happen during the construction of the needle.

Fig. 5. Width of the extended YscP₃₆₋₃₈₀ ruler's segment. Maximum (in solid line) and minimum (in dashed line) width of YscP₃₆₋₃₈₀ using a sliding window size of $n = 5$ centred at the residue i , $[i - n, i + n]$. The average maximum (0.95 nm) and minimum (0.79 nm) values are represented by constant lines. At the bottom, a cartoon representing the secondary structure is shown: grey boxes represent predicted helices, while the oval represents the position of signal 2 domain (97–137).

Discussion

There are two simple ways to explain how the length of the YscP protein could determine the length of the needle. First, as suggested earlier (Journet *et al.*, 2003), YscP could operate as a molecular ruler. In this model, YscP could stretch gradually while the needle grows, until it reaches a tension, which is transmitted to the switch domain. The switch domain then interacts with the cytosolic domain of a protein from the transmembrane export apparatus, probably YscU (Ferris *et al.*, 2005; Cornelis *et al.*, 2006; Chevance and Hughes, 2008). In this model, the actual length of the 'ruler' domain must be equal to the length of the protruding needle plus the distance separating the cytosol from the surface of the bacterium, which can be estimated around 30 nm (Macnab, 2003; Ogino *et al.*, 2006). Alternatively, one could speculate that the progressive threading of YscP from the N-terminus to the C-terminus would act as a 'timer'. In other words, export of subunits would be allowed as long as the C-terminal switch domain (the T3S4 domain) has not reached its switch partner around the translocation channel. In this model, there is a correlation between the number of residues in YscP and the needle length but the two do not need to have the same length. A slightly different version of this 'timer' mechanism was initially proposed for FliK (Moriya *et al.*, 2006). To discriminate between these two models, it would thus be interesting to have some insight into the actual length of the functional YscP.

The experiments reported in this paper show that there is a direct correlation between the number of prolines or glycines in the ruler part of YscP and the needle length, provided substitutions affected the predicted α -helical content (Fig. 2 and Table S2). The data show an inverse correlation between helical content and needle length, which supports the ruler model rather than the timer model. Indeed, helical segments contain more residues per length unit than unfolded segments. Considering the timer model, longer needles would result from a slower export of YscP and there is no obvious reason why a protein with a lower number of α -helices would be exported slower. One would eventually expect the opposite.

Therefore, we probed the actual length of the different engineered YscP proteins by using molecular simulations to calculate their extension. YscP was pulled at constant velocity mimicking the gradual extension along the needle cavity likely experienced by the protein during needle growth. As expected, the simulation results showed a strong correlation between predicted protein helical content and protein length before breaking of helices (Fig. S3). Most interestingly, the computed lengths of YscP₃₆₋₃₈₀ show a remarkable correlation with the needle lengths determined experimentally, only when considering

a model for the ruler region in which the helical content is mostly conserved (Fig. 3). Furthermore, the computed YscP₃₆₋₃₈₀ lengths could be commensurate to the experimental measures of the needle (Fig. 3 and S4). The length of YscP₃₆₋₃₈₀ was indeed approximately equal to the length of the needle protruding outside the bacterium plus ~29 nm. This is consistent with the prediction of the ruler hypothesis, assuming that the ruler does conserve its helical content to control needle growth.

Altogether, these data on protein length support the ruler model as proposed by Journet *et al.* (2003). However, this model raises a few questions. First, a ruler can only work if it recognizes both ends of the structure it has to measure. In other words, the N-terminus of YscP (i.e. signal 1, residues 1–35) should somehow interact with the growing needle. So far, there is no experimental evidence that YscP reacts with YscF and one can exclude that it reacts with the LcrV tip complex because LcrV mutants make needles of normal length (Fig. S5). This situation is different from that of the flagellum where an interaction between FliK and the hook cap was demonstrated (Moriya *et al.*, 2006). For the needle, in spite of intensive investigations, no polymerization cap was identified so far, suggesting that there could be none. The question of how would the N-terminus of YscP recognize the growing end remains thus open. A second caveat, which is often put forward, is the fact that two proteins must occupy the channel of the needle at the same time. This point must even be taken more seriously because the data presented here suggest that the proteins contain α -helices. However, as shown in Fig. 5, the width of our models of YscP makes it possible from a steric point of view to have two proteins at the time in the needle. Finally, another difficulty of the model resides in the fact that it implies that YscP and the needle subunits are translocated simultaneously across the plasma membrane. It is indeed not conceivable that the plasma membrane contains an open channel as large as the needle channel because the proton motive force would collapse. The consideration of this conceptual difficulty requires some understanding of the structure and function of the transmembrane export apparatus (YscR, S, T, U, V) and this information is, so far, totally missing.

Future work should also aim at understanding better the switch mechanism. Based on the seminal discovery of *flhB* mutations suppressing *fliK* mutations (Williams *et al.*, 1996), it is generally believed that the switch results from the interaction FliK_{C-term} : FlhB_{C-term} (Ferris *et al.*, 2005), YscP_{C-term} : YscU_{C-term} (Riordan and Schneewind, 2008). No such biochemical interaction could be detected so far for YscP or FliK. However, HpaC a non-secretable protein from *Xanthomonas campestris* which presumably acts as a T3S substrate specificity switch protein was recently shown to interact with HcrU_{C-term}, the *Xanthomonas*

homologue of YscU (Lorenz *et al.*, 2008). As there is also evidence that the C-terminus of FlhB/YscU is involved in the recognition of some classes of substrates (Sorg *et al.*, 2006; 2007) the characterization of the molecular contacts between $\text{FlhK}_{\text{C-term}} : \text{FlhB}_{\text{C-term}}/\text{YscP}_{\text{C-term}} : \text{YscU}_{\text{C-term}}/\text{HpaC} : \text{HcrU}_{\text{C-term}}$ in the export machinery appears thus as a primary goal for future research.

Interestingly, the C-terminal cytosolic domain of FlhB/YscU undergoes an autoproteolytic cleavage (Ferris *et al.*, 2005) and the 'clock' model proposes that this cleavage could set the time for export of early substrates (Moriya *et al.*, 2006). However, a detailed molecular analysis of the reaction showed that cleavage, which occurs immediately after translation and folding in the cytoplasm, is a critical event for stabilization of these inner membrane proteins and thus that is not the switching event *per se* (Zarivach *et al.*, 2008).

To summarize, the data presented here suggest that YscP maintains its helical secondary structure while exerting its function and provide support for the ruler model but more information is required to fully understand the needle length control mechanism.

Experimental procedures

Bacterial strains, genetic constructs and sequence analyses of yscP from wild-type strains

The different wild-type *Y. enterocolitica* strains and the plasmids encoding the different *yscP* genetic constructs used in this study are listed in Table S1. They were engineered according to standard procedures described in Sorg *et al.* (2007) using the oligonucleotides listed in Table S3.

The *yscP* gene from different wild-type strains was amplified by PCR from pYV plasmid preparations (HiSpeed Plasmid Mini kit, Qiagen) using the Pfu turbo polymerase (Startagene) and primers 3344 and 3345. The PCR products were analysed by agarose gel electrophoresis and purified from the gel with the Gel extraction kit (Sigma). Both strands of each PCR product were sequenced using a 3100-Avant genetic analyzer (ABI Prism) and the following oligonucleotides 3344, 3345, 3321, 3170, 3171 and 3672 (see Table S3).

Induction of the yop regulon, Yop protein analysis and needle length measurement

Bacterial cultures, induction of injectisomes synthesis and protein analysis was done as described in Sorg *et al.* (2007). YscPwt was overexpressed downstream the pBAD promoter in *Y. enterocolitica* E40 ΔyscP (LJ4036). Bacteria were analysed after 4 h of induction of the *yop* regulon at 37°C. The pBAD promoter was induced by adding 0.2% L-arabinose just before the shift to 37°C, and again 2 h later. Bacteria were harvested at 2000 g and resuspended gently in 20 mM Tris-HCl, pH 7.5. Droplets were applied for 1 min to freshly glow-discharged, formvar-carbon coated grids, and negatively

stained with 2% (w/v) uranyl acetate. Bacteria were visualized in a Philips CM100 transmission electron microscope at a nominal magnification of 20 000 \times and an acceleration voltage of 80 kV. Sizes were measured with the 'Soft imaging system software' (Hamburg, Germany). For the statistical analysis, a *t*-test comparing the measurements of the mutants to those of the wild type was performed using the Macintosh Version of GraphPad Prism 5.0a (Trial) from Software MacKiev.

In silico molecular modelling of the YscP protein

We obtained information about YscP secondary structure for the wild type using several secondary structure predictors (see Fig. S6) and designed mutagenesis experiments and modelling based on these results. We did not get a full consensus for all the algorithms taken into account; nevertheless most of them predicted a significant helical content for YscP, with good topological similarity. We chose SIMPA96 (Levin *et al.*, 1986) prediction as initial working hypothesis to interpret the results from mutagenesis experiments and molecular simulations as described below, obtaining a consistent match for the designed mutants that were supposed to break and/or form helical structure. This can also be taken as a *posteriori* indirect validation of the initial predicted helical content. These results were initially used to design the experiments on the wild type and Pro/Gly-variants of YscP. In a second stage, we sculpted based on the same information structural models of the ruler regions (from amino acid 36–380). Said models represented a partially extended protein with intact helices intercalated by unstructured coiled regions. YscP_{36–380} models for wild type and its 9 Pro/Gly-mutants have been pulled ~20 times *in vacuo* at the constant velocity of 0.001 nm ps⁻¹, using steered MD (Izrailev *et al.*, 1998) as implemented in NAMD molecular dynamics engine (Izrailev *et al.*, 1998). CHARMM force field is used to describe the YscP protein (MacKerel *et al.*, 1998). In each simulation, pulling force, helical content [determined using the DSSP algorithm (Kabsch and Sander, 1983)] and strand length are evaluated. The choice of simulating the protein *in vacuo* has been determined by the following reasons: (i) preliminary results showed that no relevant differences from results *in vacuo* could be obtained by performing the steered MD in any of the available implicit solvent models; (ii) given the length of the models (over 80 nm), the same set of simulations with the use of an explicit solvent model would have been computationally prohibitive. However, a limited set of steered MD simulations has been carried out for relevant conformations to estimate the difference on the calculated YscP length provided by neglecting explicit solvent. The wild type along with the two most extreme proline variants (+8P and -8P mutants) were simulated in explicit solvent using a TIP3P model for water. The results from single trajectory MD are also reported in Fig. 3 and Table S2, and pointed to an identical, within errors, length estimation and correlation with experimental measurements. We assessed the protein length upon unfolding of its helices by measuring the distance between the two terminal C α -atoms (residues 36 and 380). We decided to assess the decrease of helical content during the pulling in order to determine univocally the beginning of helical unfolding. This could be achieved by counting the number h_n of residues

being part of a helix for every frame of the simulation and comparing it to the number h_i initially present in the protein. Unfolding was determined as soon as $h_i^*t > h_m$, where t is a threshold percentage. The choice of the correct threshold t being crucial, we assessed how the measure of protein length is affected by this value. We performed the measurements with a value of t between 0.8 and 0.95 and, it turned out that the outcome of the evaluation was not significantly affected by this value. This indicated that the breaking of helices is quite abrupt. For the rest of the analysis we set $t = 0.9$.

Acknowledgements

We thank Cécile Paroz for sequencing the wild-type *yscP* genes, Yaniv Cohen for generating the *lcrV* null mutant, Gianni Morson for assistance in electron microscopy and G. Wauters (Louvain) for the gift of the wild-type *Y. enterocolitica* strains. This work was supported by the Swiss National Science Foundation (Grant 310000-113333/1 to G.C.).

How many YscP molecules are needed to control length of one injectisome needle?

The *Yersinia* injectisome needle is determined by only one molecule of YscP

Author contributions

SW and GC conceived and designed the experiments. SW and LM performed the experiments. SW, LM and GC analyzed the data. SW and GC wrote the paper. MS and MDP performed modeling and contributed to writing the paper.

The needle length of the *Yersinia* spp. injectisome is determined by YscP, an early substrate of the injectisome itself. There is a linear correlation between the length of YscP and needle length and thus it has been suggested, that YscP acts as a molecular ruler to control needle length. However, it is not clear whether one single molecule of YscP controls the length of one needle or whether several molecules of YscP are required for length determination of the *Yersinia* injectisome needle. In this dynamic ruler model YscP molecules are exported in alternation with the needle subunit YscF until the needle length matches the ruler length, which would result in a stop of needle growth. To address this question, bacteria expressing simultaneously a short and a long version of YscP were engineered. The experimentally obtained needle length distribution was analyzed mathematically and compared to the distributions predicted by mathematical modeling of the various possible scenarios. The experimental data are compatible with the single ruler model and not with the scenarios involving more than one ruler per needle.

Control of the length of the injectisome needle requires only one molecule of YscP

Running title: One ruler per needle.

Subject category: Microbiology & Pathogens

ABSTRACT

The needle length of the *Yersinia* spp. injectisome is determined by YscP, an early substrate of the injectisome. It is proposed that YscP acts as a molecular ruler coupled to a substrate specificity switch but some data are missing to propose a precise mechanism. Here, by measuring needles made by *Yersinia enterocolitica* that express simultaneously a short and a long version of YscP, we provide evidence that only one molecule of YscP is required to control the length of one needle.

Keywords: nanomachine / type-III secretion / molecular ruler/ *Yersinia*

INTRODUCTION

The injectisome or needle complex allows pathogenic bacteria to inject effector proteins across eukaryotic cell membranes, a process called type III secretion (T3S). This nanomachine is evolutionary related to the flagellum and has a basal body made of several rings embedded in the two bacterial membranes (Hodgkinson *et al.*, 2009; Marlovits *et al.*, 2006) and including integral membrane proteins constituting the core of the T3S export apparatus (reviewed by (Cornelis, 2006; Galan & Wolf-Watz, 2006; Yip & Strynadka, 2006)). The *Yersinia enterocolitica* E40 Ysc injectisome terminates with a 65-nm long stiff hollow needle, made of ~ 140 copies of the 9-kDa YscF protein. At the tip of the needle, a pentamer of LcrV (Broz *et al.*, 2007; Mueller *et al.*, 2005) forms a structure serving as an assembly platform for the translocation pore (Goure *et al.*, 2005).

During morphogenesis, the needle components, like the hook and the filament of the flagellum are sequentially exported by the T3S apparatus itself, travelling through the growing structure and polymerizing at its distal end (Macnab, 2003). The export apparatus is expected to switch its substrate specificity over time so that needle subunits (early substrates) are exported before LcrV (intermediate substrate) and the effectors (late substrates). The switch between early and intermediate substrates determines the arrest of needle growth and hence the needle length (Ferris & Minamino, 2006).

The control of the needle length and the switch to export intermediate substrates involves a protein, which is itself exported, YscP for the *Yersinia* spp injectisome (Journet *et al.*, 2003) and FliK for the flagellum (Hirano *et al.*, 1994; Minamino *et al.*, 1999; Minamino *et al.*, 2004). In the absence of this protein, injectisomes have extra-long needles (deregulated phenotype) and do not secrete LcrV and effectors, while the flagellum has extra-long hooks and no filament (polyhook phenotype). The switch function is assigned to the C-terminal domains of YscP and FliK (Agrain *et al.*, 2005a; Minamino *et al.*, 2004). This domain, called T3S4 for Type 3 Secretion Substrate Specificity Switch (Agrain *et al.*, 2005a) is thought to interact with YscU (FlhB in the flagellum), a component of the basal body that is also involved in setting the hierarchy of export (Botteaux *et al.*, 2008; Hirano *et al.*, 1994;

Sorg *et al.*, 2007). To control length, YscP needs to be exported by the nascent T3S export machine, a phenomenon driven by two independent N-terminal export signals (S1: residues 1-35 and S2: 97-137) separated by a short spacer (Agrain *et al.*, 2005b).

The central region of YscP is proline-rich and contains repeats whose number varies from strain to strain in the genus *Yersinia* (Journet *et al.*, 2003; Wagner *et al.*, 2009). Deletions between residues 36-96 and 222-306 of YscP and insertions between residues 49 and 50 lead to shorter and longer needles, respectively, with a linear correlation between the size of YscP and the needle length, which led to a model where YscP acts as a molecular ruler measuring the needle (Journet *et al.*, 2003). A similar correlation, observed between the size of FliK and the length of the hook (Shibata *et al.*, 2007) was recently re-interpreted in the same way (Hirano *et al.*, 2009).

The ruler model implies that the actual length of the ruler domain of YscP matches the length of the needle plus the basal body. The length of the ruler domain calculated by molecular modelling was indeed found to correlate with the measured needle length, with a constant difference of 29 nm, which corresponds approximately to the size of the basal body (Wagner *et al.*, 2009). This element thus reinforces the ruler model. Still, open questions about the details of the mechanism remain. The first model to be proposed (Journet *et al.*, 2003) was static, in the sense that each needle is regulated by a single ruler molecule which gradually stretches and switches substrate specificity when the needle has reached its final length and the T3S4 domain is in the right position to interact with the secretion apparatus and thereby terminate needle elongation. In this model, the YscF proteins are able to pass through the growing needle which is partially filled by YscP. A dynamic model was then proposed, in which the elongation of each needle is controlled by several rulers or "tape-measure" molecules which keep passing through the still growing needle. When the actual needle length exactly matches (or is greater than) the length of the passing ruler molecule, the latter stops elongation (Cornelis, 2006; Moriya *et al.*, 2006). In this model, needle subunits and ruler or tape-measure proteins travel alternatively. In this report, we provide some genetic evidence that only one molecule

of YscP is required to control the length of one injectisome needle, which supports the static model.

RESULTS

Rational of the approach and selection of the appropriate alleles

Our approach consists in measuring the needles made by partial diploid bacteria that express simultaneously two yscP alleles -a short one and a long one- and compare the distribution of needle length to the predictions made by a mathematical analysis of the two models. As a short YscP protein, we chose YscP₃₈₈, a derivative of YscP in which the spacer between the two export signals and one copy of the repeats in the central part have been removed (Fig 1A) (Journet *et al.*, 2003). To generate a long YscP, we engineered a restriction cleavage site between codons 250-251 in the central part of the yscP gene. We then generated yscP₆₈₆ by inserting a copy of codons 214-374, encoding the repeated region, into the restriction site (Fig 1A). The two recombinant genes, cloned on the same expression vector were then introduced in *Y. enterocolitica* LJ4036 deleted from the wt copy of yscP and the phenotypes were analyzed (Fig 1B). To test whether the two sorts of needles could be discriminated, equal numbers of *Y. enterocolitica* LJ4036 bacteria producing either YscP₃₈₈ or YscP₆₈₆ were mixed and 200 needles were measured. As shown in Fig 1C, the histogram of needle length distribution (nld) revealed two distinct peaks, at the expected sizes of 48 ± 6 nm and 100 ± 12 nm. Surprisingly, even though equal amounts of bacteria were mixed, about 60% of the needles measured were of the small type (Table S3). The reason for this unequal representation was not investigated. We can nevertheless exclude that long needles break down because no small needles appear in cultures producing exclusively long needles (Fig 1C).

Predicted nld for diploid bacteria according to the static and dynamic models.

In a first step, the nld of haploid bacteria was analyzed and found consistent with a normal distribution (Figs S3, Tables S3, S4). Based on this, an algorithm was developed to account for the static and dynamic models of needle length control

(see SI for details). The one ruler per needle model (scenario 1) predicts (Scheme S1) that (i) diploid bacteria will produce a mixture of long and short needles identical to a mixed culture of two different haploid strains (Fig 2A, Tables S5-S7) and that (ii) there will not be any deregulated needle

In the case of the dynamic ruler model, two scenarios can be envisioned; needle growth is interrupted when the length of the YscP travelling molecule is shorter than the needle (scenario 2), or YscP exactly matches (within a tolerance) the needle length (scenario 3). The nld was computed (Scheme S2) for scenarios 2 and 3, using ratios of $[YscF]/[YscP]$ ranging from 1 (~100 YscP/needle) to 50 (~3 YscP/needle) (Fig S7). The $[YscF]$ and $[YscP]$ terms represent the “effective concentration” of needle subunits and proteins, respectively (see SI material); their ratio represents the relative probability of accessing the basal body. Ratios of $[YscF]/[YscP]$ below 1 were considered unrealistic and not included. Full results are given in Fig 2 and S6, where the number of needles is shown as a heat map (Fig 2B, 2D). Significant slices for scenario 2 and 3 are given in Figs 2C and 2E, respectively. The percentage of rulers belonging to either the long- or short-needle distribution is also reported along with the percentage of deregulated needles produced by the model (Figs 2B and 2D).

For scenario 2, when the “effective concentration” of rulers is similar to that of needle subunits ($[YscF]/[YscP] \approx 1$), the system is “over-regulated” by the short rulers which meet the stopping criterion (i.e., needle length greater than the ruler length) before the longer ones. This is evident in Figs 2B and S6A, B where a sole peak (corresponding to the smaller needles) is present for low $[YscF]/[YscP]$ values. As $[YscP]$ decreases ($[YscF]/[YscP]$ up to 50), the initial peak broadens. Nonetheless, two distinct peaks were never observed, as confirmed by the Expectation-Maximization Algorithm (EMA) (Georgi *et al.*, 2010) analysis (Figs 2B, C and S4, S6A, C and Table S8). Since this scenario imposes a stop whenever the needle length is greater than the passing-by ruler, even needles allowed to grow by a low measurement frequency (low $[YscP]$) will be stopped as soon as a ruler is allowed to enter the needle. Hence the scenario excludes the appearance of deregulated needles (Figs 2B, S7A).

For scenario 3, “over-regulation” by the small ruler is observed when $[Y_{scF}]/[Y_{scP}] \approx 1$ (Fig 2C, S6B, D). As the measurement frequency decreases with lower values of $[Y_{scP}]$, two distinct peaks do appear in correspondence, respectively of short and long needle distributions. For values of $[Y_{scF}]/[Y_{scP}]$ above ~ 30 , the computed nld is compatible with normal bimodal distribution (Table S9, Fig S5). Below this threshold the computed distributions are unlikely to be either normal or bimodal (Fig S7). The stopping rule is more restrictive than in scenario 2, allowing for growth interruption only when the needle length is equal (with a tolerance) to the passing-by ruler length. As $[Y_{scP}]$ decreases the number of deregulated needles rapidly increases (Fig S7B) (see SI material for details). Thus, scenario 3, in contrast to scenario 2, features an increasing number of deregulated needles for low $[Y_{scP}]$ (Fig 2E, S7). As an example, scenario 3 produces 29% deregulated needles when the ratio of $[Y_{scP}]/[Y_{scF}]$ is 1/40, i.e., when there are less than 5 Y_{scP} per needle (Figs 2D, E and S7).

Diploid strains for short and long *yscP* alleles produce two distinct populations of regulated needles and no deregulated needles.

Three different types of genetic constructs were engineered. First, the *yscP*₃₈₈ allele was inserted on the 70-kb virulence plasmid by allelic replacement of the wt gene and the *yscP*₆₈₆ allele was introduced *in trans* on an expression vector, downstream from the strong pBAD promoter (Fig 3A). In *Y. enterocolitica* E40, under the conditions used, this vector leads to a detectable expression in every bacterial cell (Fig S6). Both Y_{scP} proteins were produced and secreted by the diploid bacteria but the long variant was more abundantly secreted (Fig 4A). The needle length histogram revealed two peaks at 54 ± 6 and 98 ± 15 nm, similar to those obtained with haploid bacteria (50 ± 5 nm and 103 ± 12 nm)(Fig 4A).

In the second type of construct, the two alleles were placed on the same pDuet expression vector, each of them downstream from an individual T7 promoter (Fig 3B). As shown in Fig S7, *egfp* and *mCherry* cloned together on this vector were simultaneously expressed in every bacterium. In order to avoid any bias due to the respective position of the alleles on the pDuet, the two *yscP* alleles were cloned in

each position, generating two different expression plasmids (e.g., pLM18 and pM20, Fig 3B). The recombinant plasmids were introduced into the $\Delta yscP$ strain LJ4036 together with a plasmid encoding an inducible T7 polymerase. Synthesis of YscP was induced at the same time as type III secretion. Plasmid pLM20 seemed to drive more export of the long YscP than plasmid pLM18 (Fig 4B). For both constructs, the histograms of needle lengths revealed a clear peak of short needles (50 ± 8 nm and 48 ± 6 nm) similar to the needles produced by haploids (48 ± 6 nm and 50 ± 6 nm) besides a peak of longer needles (106 ± 12 and 99 ± 12 nm), also similar to the needles produced by the corresponding haploids (110 ± 10 and 107 ± 14 nm) (Fig 4B).

Finally, both alleles were fused in a single operon, downstream from the pBAD promoter (Fig 3C). There were again two populations of needles (50 ± 6 nm and 91 ± 13 nm) similar to those produced by the corresponding haploids (48 ± 5 nm and 103 ± 12 nm) (Fig 4C and Table S10).

Deregulated needles were never observed in eight different experiments with the four different constructs (Fig 4). The results were then pooled (1521 measurements) and found consistent with a bimodal normal distribution (EMA analysis in Tables S10, S11). As shown in Fig 5, two distinct peaks account for short and long needle populations and are clearly consistent with the predicted distributions found for scenario 1 and 3 (Fig 2A, E). However, scenario 3 is inconsistent with the experimental results since it predicts a significant percentage of deregulated needle (Fig 2E) whereas none was experimentally observed. The experimental data closely match the predicted distribution of scenario 1.

The proportion between the number of long and short needles reflects the proportions of long and short YscP molecules.

With all three different constructs, the proportion of long needles was always smaller than that of short needles as seen in the proof of principle experiment where equal numbers of bacteria producing either short or long molecules were mixed (Table S3). This probably results from the same bias. However, for LJ4036 (pLM20) secreting more of the long YscP version than LJ4036 (pML18), the proportion of long

needles was higher (~ 40% versus ~ 30%, Fig 4 and Table S10) than for LJ4036 (pML18). This data suggests that there is a correlation between the amount of needles of one type and the amount of ruler of that type that is secreted.

DISCUSSION

In this work, we measured the needles assembled by *Y. enterocolitica* bacteria producing simultaneously a short and a long version of the ruler protein. We ensured that both proteins were synthesised in every bacterium and readily exported. The experiment was done with three different kind of genetic constructs in order to exclude any bias due to a preferred transcription or translation of one allele versus the other. The three different *Y. enterocolitica* diploid bacteria produced a mixture of short and long needles. The length of the short and long needles corresponded exactly to the length of the needles produced when only one type of ruler was produced. The interpretation of these data is that only one molecule of ruler determines the length of one needle. Indeed, if more than one ruler were involved, depending on the exact mechanism, mathematical modeling predicts the appearance of intermediate sized or deregulated needles. In addition, with one genetic construct, we observed that more export of the long ruler correlated with more long needles. These two types of observations reinforce the molecular ruler model, based on the correlation between the needle length and the length of the control protein (Journet *et al.*, 2003; Wagner *et al.*, 2009).

The present conclusion that only one ruler determines the length of one needle may seem to be at odds with our previous observations that over-expression of YscP improves the needle length control (Agrain *et al.*, 2005b; Sorg *et al.*, 2007). However, these observations were made, with systems in which export of YscP was reduced, either because one export signal was missing (Agrain *et al.*, 2005b) or because YscU was mutated (Sorg *et al.*, 2007). In these systems, over-expression of YscP only restored export of YscP to wt levels.

However, two aspects of the model remain to be investigated. First, the N-terminus of YscP, which is most likely exported first (Agrain *et al.*, 2005b), needs to interact with the growing end of the needle. In good agreement with this prediction,

the N-terminus of the flagellum hook-length control protein FliK interacts with the hook cap protein, the protein located at the tip of the hook during elongation (Moriya *et al.*, 2006). However, this observation cannot be simply extrapolated to the injectisome needle because no capping protein has been identified so far at the end of the growing needle. The mature needle terminates with a tip structure made of LcrV (Mueller *et al.*, 2005) but the needle length is controlled in the absence of LcrV (Wagner *et al.*, 2009), meaning that the length control protein must interact with a tip-less needle. The question of the ruler anchor is thus unanswered but one cannot exclude that YscP attaches to the needle end since it is detectable at the bacterial surface by immuno-gold labeling (Stainier *et al.*, 2000).

MATERIAL AND METHODS

Bacterial strains, plasmids, oligonucleotides, and details of the mathematical modeling are described in the Supplementary Online Information. Induction of the *yop* regulon, Yop protein analysis and needle length measurement were as described in Wagner *et al.*, 2009. Detached needles were measured.

Figure 1

Selection and analysis of the alleles used in this study.

Schematic representation of two *yscP* genes (*yscP*₃₈₈ and *yscP*₆₈₆) cloned downstream from the pBAD promoter in pCA20 and pSTW14, respectively (A). Export of YscP by *Y. enterocolitica* E40 wt and LJ4036 (called $\Delta yscP$) over-expressing YscP wt (from pLJ6), YscP₃₈₈ (from pCA20) or YscP₆₈₆ (from pSTW14) and a 1:1 mixture of bacteria over-expressing YscP₃₈₈ and YscP₆₈₆. Supernatant fractions (SN) were analyzed by immunoblotting using anti-YscP polyclonal antibodies (B). Histogram representation of the needle length distribution normalised to unity; a Gaussian function of experimental mean and st. dev. (black line) and the best fitting Gaussian (red line) are reported for haploids; a double Gaussian function obtained by EMA is reported for mixed samples, n, number of measured needles (C).

Figure 2

Nld predicted for the static and dynamic models.

Histogram representation of the normalized (area below the curve equated to 1) needle length distribution (nld) computed for the scenario 1 (A). Needle populations obtained for scenario 2 (B) and 3 (D), with the nld calculated at different values of $[Y_{scF}]/[Y_{scP}]$ and reported as a not-normalized heat map representing the number of needles (see also Fig S6). Needle distribution among the short (red line), long (blue line) and deregulated (black line) species computed for scenario 2 and 3 are reported in the right-handed insets. Histogram representation for the nld obtained at significant value of $[Y_{scF}]/[Y_{scP}] = 40$ for scenario 2 (C) and 3 (E) are reported along with their bimodal normal distribution fitting as obtained by EMA analysis. Green dotted lines placed at the centre of each peak identify the mean value of each population belonging to the overall bimodal distribution.

Figure 3

The various genetic constructs expressing *yscP₃₈₈* and *yscP₆₈₆*.

pLJ4022 is the 70-kb virulence plasmid where *yscP₃₈₈* replaces the wt allele, downstream from its natural promoter. pSTW14 encodes YscP₆₈₆ from the pBAD promoter (A). The six derivatives of pCDFDuet (four haploids and two diploids) are shown in panel B. In pSTW65, the two alleles are cloned as one operon downstream of the pBAD promoter (C).

Figure 4

Experimental nld in bacteria expressing *yscP*₃₈₈, *yscP*₆₈₆ or both.

On the left, supernatant (SN) fractions were analyzed by immunoblotting using anti-YscP antibodies. On the right, nld of the needles from diploid and the corresponding haploid bacteria. Panels A, B and C show the data for the genetic constructs shown in panels A, B and C from Fig 3, respectively. The histogram representation is normalised to unity. A Gaussian function of experimental mean and st. dev. (black line) and the best fitting Gaussian (red line) are reported for haploids; a double Gaussian function obtained by EMA is reported for diploid samples. n, number of measured needles; p, Promoter; P, Peak.

Figure 5

Experimental nld compared to predicted nld according to the different scenarios.

Histogram representation of the nld obtained with the four different diploid constructs (histogram binning size = 5 nm) (A). The normalized experimental nld is fitted by a bimodal normal distribution as obtained by the EMA analysis (blue line), and superimposed to the bimodal normal distributions obtained for the different three computed scenarios. Bimodal normal distribution fits are here weighted to match the experimental ratio found between long and short needle populations in a mixture of cultures producing short and long needles. (see Table S11).

Supplementary Figure S1

Expression of the egfp gene cloned downstream from the pBAD promoter in *Y. enterocolitica* E40.

Y. enterocolitica strains were inoculated to an O.D.₆₀₀ of 0.1 and cultivated in brain-heart infusion (BHI; Remel) supplemented with 35 $\mu\text{g/mL}$ nalidixic acid, 4 mg/mL glycerol, 20 mM MgCl_2 and 20 mM sodium oxalate (BHI-Ox) 2 h at RT, then shifted to 37 °C and incubated for 4 h. Ampicillin was used at a concentration of 200 $\mu\text{g/mL}$ to select for the expression plasmids. Expression of EGFP was induced by adding indicated amounts of arabinose to the culture just before the shift to 37 °C, and again 2 h later. EGFP expression was analyzed by fluorescence-activated cell sorter (FACS) analysis. After incubation at 37 °C for 4 h, 1 mL of bacterial cultures were centrifuged for 1 min at 20817 g and bacterial pellets were resuspended and adjusted to an O.D.₆₀₀ of 0.2 in 1 mL PBS, prior to FACS analysis. FL1-H, Intensity of fluorescence; % of Max, % of bacteria.

Supplementary Figure S2

Expression of *egfp* and *mCherry* cloned in the two expression loci of pDuet in *Y. enterocolitica* E40.

Y. enterocolitica strains were inoculated to an O.D.₆₀₀ of 0.1 and grown in brain-heart infusion (Remel) supplemented with 35 µg/mL nalidixic acid, 200 µg/mL Ampicillin, 50 µg/mL Streptomycin, 4 mg/mL glycerol, 20 mM MgCl₂ and 5 mM CaCl₂ for 2 h at RT. Expression of the T7 polymerase was then induced with 0.1% arabinose. Ten minutes later, expression of EGFP and mCherry was induced with 800 µM IPTG at RT for 3 h. For fluorescence imaging, cells were placed on a microscope slide layered with a pad of 2% agarose dissolved in water. A Deltavision Spectris optical sectioning microscope (Applied Precision, Washington, United States) equipped with an UPlanSApo 100x/1.40 oil objective (Olympus, Japan) and a coolSNAP HQ CCD camera (Photometrics, AZ, United States) was used to take differential interference contrast (DIC) and fluorescence photomicrographs. FITC filter sets (Ex 490/20 nm, Em 528/38 nm) and Rhodamine filter sets (Ex 555/28 nm, EM 617/73 nm) were used for EGFP and mCherry respectively. Exposure times were 0.15 s for DIC and 1.0 s for fluorescence frames. Per image a Z-stack containing 20 frames per wavelength with a spacing of 150 nm was acquired. Images at the median of the cell were chosen and processed with softWoRx v3.3.6 (Applied Precision, WA) and ImageJ (National Institute of Health, USA) software.

Supplementary Figure S3

Histogram representation of the (normalized on the right) nld obtained upon expression of the two rulers

Histogram representation of the (normalized on the right) nld obtained upon expression of the two rulers (histogram binning size = 5 nm). A) Short ruler: YscP₃₈₈. B) Long ruler: YscP₆₈₆. C) Sample created by mixing organisms containing both the short and the long ruler. The black line in A and B represents a Gaussian function plotted using the experimental mean and standard deviation as centre and width, respectively. The red line in A and B represents a Gaussian whose centre and widths have been optimized to match the experimental nld. The blue line in C is a “double Gaussian” plotted using the parameters obtained by applying the EMA on the experimental nld. (left side: non-normalized; right side: normalized)

Supplementary Figure S4

SUPPLEMENTARY INFORMATION

Supplementary Material and Methods

Bacterial strains and plasmids

This work was done with *Y. enterocolitica* E40 (Sorg *et al.*, 1995). Bacterial plasmids and genetic constructions are listed in Table S1. Plasmids were generated using either Pfu turbo polymerase (Stratagene) or Vent DNA polymerase (New England Biolabs). The oligonucleotides used for genetic constructions are listed in Table S2. All constructs were confirmed by sequencing using a 3100-Avant genetic analyzer (ABI Prism).

Induction of injectisome assembly and analysis of YscP proteins

Y. enterocolitica E40 bacteria were grown in liquid brain-heart infusion (BHI; Remel) medium. Induction of the *yop* regulon was done as described in ref (Sorg *et al.*, 2007). Yop proteins from the supernatant were analyzed by SDS-PAGE. For detection of YscP in total cells, 1.6×10^7 bacteria were loaded per lane. For YscP detection in supernatants, the supernatants from 1.6×10^8 bacteria were loaded per lane. Immunoblotting was done using a polyclonal rabbit anti-YscP antibody (1:3000; MIPA57) as described in ref (Sorg *et al.*, 2007). Expression of the different *yscP* genes cloned downstream from the pBAD promoter was induced by adding 0.2% arabinose to the culture just before the shift to 37 °C, and again 2 h later. Ampicillin was used at a concentration of 200 µg/mL to select for the expression plasmids and instead of glucose, glycerol was used as carbon source at a final concentration of 4 mg/mL. Expression of the *yscP* genes cloned downstream from the T7lac promoter was induced by adding 800 µM IPTG to the culture just before the shift to 37 °C. Expression of the T7 RNA polymerase gene cloned downstream of the pBAD promoter was induced by adding 0.1% arabinose to the culture 10 min before the shift to 37 °C. Streptomycin at a concentration of 50 µg/mL was used to select for the expression plasmids. Expression of the T7 RNA polymerase gene cloned downstream of the pBAD promoter was induced by adding 0.1% arabinose to the culture 10 min before the shift to 37 °C.

Needle length measurement

Visualization of needle-like structures was done by transmission electron microscopy as described in Hoiczky & Blobel, 2001 and Sorg *et al.*, 2007. Detached needles were measured.

Mathematical analysis

The needle length distribution (nld) of needles produced by haploid bacteria is Gaussian

YscP₃₈₈ and YscP₆₈₀ were chosen as, respectively, short and long ruler. The nld of each (Tables S3, S4) was recorded and reported in Figure S3A,B in histogram representation, with a bin size of 5 nm. By visual inspection both distribution appeared to be Gaussian-shaped. To give a quantitative measure of the distribution ‘normality’ two approaches have been adopted: a) the mean and standard deviation of the two samples have been used, respectively, as the centre (μ) and width (σ) of a Gaussian function (Equation 1); b) for each distribution a value for μ , σ were obtained by fitting a Gaussian function on the experimental nld. To compare a continuous Gaussian function to a discrete distribution a simple strategy was devised: the number of needles in the i^{th} bin (height of the i^{th} histogram), indicated as H_i in Equation S2, is compared with the value the Gaussian function assumes in correspondence of the middle point of the i^{th} bin, indicated as $G(x_i)$ in Equation S2. The computed value of the error E was used to quantify the agreement of the experimental discrete length distribution with Gaussian functions. For both the short and long ruler the nld was in good agreement with the experimentally derived (black line, Figure S3A,B) and with the optimized Gaussian (red line, Figure S3A,B), as confirmed by: a) similar values of the computed errors E , b) mean and standard deviation of the samples compare fairly good with, respectively, centre (μ) and width (σ) of the optimized Gaussian functions.

$$G(x) = \frac{1}{\sigma\sqrt{2\pi}} e^{-\left(\frac{(\mu-x)^2}{2\sigma^2}\right)} \quad \text{Equation S1}$$

$$E = \sum_{i=1}^n (G(x_i) - H_i)^2 \quad \text{Equation S2}$$

The nld of needles produced by a 1/1 mixture of cultures of haploid bacteria is Gaussian

As explained in the main text, to test whether the two kinds of needle could be discriminated, bacteria producing either YscP₃₈₈ or YscP₆₈₆ were mixed and the length of the expressed needles measured. The histogram nld, reported in Figure S3C, revealed two distinct peaks compatible with a bimodal distribution. Since a bimodal distribution can be expressed, if the constituting peaks are far apart, as a mixture of two unimodal distributions, a “double-Gaussian” function (G_2 , see Equation S3) was used to fit the experimental nld. Since a standard parameter fitting of the G_2 function failed, due to the simultaneous presence of parameters within and outside the exponential part of G_2 , a more robust and sophisticated procedure, based on the “Expectation-Maximization” Algorithm (EMA), was employed to determine the centre and the width of each of the two constituting Gaussian functions and their respective weight (parameters c_1 and c_2 in Equation S3). Moreover this approach yielded a quantitative esteem for the likelihood relating the experimental distribution and the best parameters of the proposed Gaussian mixture model. By applying the EMA procedure to the experimental nld, the two peaks were placed at 47.5 ± 6.1 nm and 101.6 ± 13.5 nm, respectively (Table S5), in good agreement with the values found for the un-mixed haploid nld (see Figure S3 and Tables S1-3 for comparison).

$$G2(x) = c_1 \frac{1}{\sigma_1 \sqrt{2\pi}} e^{-\left(\frac{(\mu_1 - x)^2}{2\sigma_1^2}\right)} + c_2 \frac{1}{\sigma_2 \sqrt{2\pi}} e^{-\left(\frac{(\mu_2 - x)^2}{2\sigma_2^2}\right)}, (c_1 + c_2 = 1)$$

Equation S3

As explained in the main text, when equal amount of bacteria were mixed, about 60% of the measured needles were of the small type (Table S6). This has been attributed to a systematic error of the measure. The nld recorded for a set of needle belonging to each sample was processed by using the EMA; the optimized Gaussian mixture ($G2_{opt}$) of each set was used to separate the measured needles in two groups according to their length. A clustering tool based on EMA Gaussian mixtures was employed to assign the needles either to the “short” or to the “long” group.

It should be noted that neither for the separately measured haploids nor for their mixture were “unregulated” needles observed.

Relation between needle length and number of needle subunits

On the basis of the “static” and “dynamic” models for needle length regulation, an algorithm was assembled to generate needle length distributions according to the assumptions associated to the proposed models. The reliability of the various models was assessed by comparing the computed length distributions with the ones experimentally measured for partially diploids organism.

The devised algorithm makes use of the experimental nld of short and long needles expressed in haploid organisms. It is assumed that the YscP₃₈₈ ruler generates a population (P_1) of needles with mean $M_1 = 49.0$ nm and standard deviation $SD_1 = 5.5$ nm (Table S3), while the YscP₆₈₆ ruler yields a population (P_2) of needles with mean $M_2 = 105.7$ nm and standard deviation $SD_2 = 13.4$ nm (Table S4).

The approximate length of one needle subunit ($L_0 = 6.3$ nm) and the unitary contribution of each subunit ($L = 0.45$ nm) to the overall needle length were calculated on an atomistic structural model of *Y. enterocolitica* T3SS needle, as built by homology modeling from the data available for Shighella (Deane et al, 2006). According to this model the needle features a helicoidal arrangement, each turn being formed by about 6 subunits, each one shifted with respect to the previous one by L (along the growth axis); for a needle composed by n subunits the total length is thus given by Equation S4.

$$L_{tot} = L_0 + (n - 1)L$$

Equation S4

Stochastic method:

Mathematical algorithm for the static model (Scenario 1)

According to the static model the length of each needle is regulated by a single ruler molecule fastened to the cytoplasmic side of the basal body with the T3S4 domain and hooked to the growing end of the needle by the S1/S2 domains. The ruler is eventually released and the T3SS machinery stops exporting needle subunits (YscF protein) thus terminating needle growth. In this model the length of each needle is directly determined by the length of the ruler protein, to which both the mean and the standard deviation of the overall needle population are directly related.

In an organism endowed by a duplicate set for yscP gene (partial diploid), two variant of the YscP protein (YscP₃₈₈, YscP₆₈₆) of different length were expressed.

There is competition between the two rulers in negotiating their access to the basal body as to exert their function. The probability for one ruler to enter the basal body instead of the

other is a function of their relative expression levels, diffusion constants, export apparatus association and recognition coefficients, and other unknown factors. The “ruler effective concentration”, $[YscP_{388}]$ and $[YscP_{686}]$, can be thus defined as a global parameter counting in, for each ruler, all known and unknown factors, including their actual molar concentration in the cytoplasm.

In the static model there is no competition between the needle subunits and the ruler proteins to access the basal body entrance, since the YscF proteins are exported while the YscP is stably positioned as described above. This implies that the YscF proteins are capable of passing through the channel constituted by the hollows in both the basal body and growing needle. Since this channel accommodates the (partially extended) YscP protein, for the needle subunits to pass a partial unfolding of either or both YscF and YscP protein could be required.

In the mathematical representation of the static model, the “ruler effective concentrations” $[YscP_{388}]$ and $[YscP_{686}]$ were given a statistical interpretation, their ratio R_{SL} (Equation S5) being considered as the bias favoring one ruler over the other in entering the export apparatus and exerting a measuring function.

The algorithm for generating the static model nld on the basis of these assumptions is given in Scheme S1:

$$R_{SL} = [YscP_{388}] / [YscP_{686}] \quad \text{Equation S5}$$

Scheme S1. Algorithm employed to obtain a nld according to the assumptions contained in the static model (Scenario 1).

- 1)** Input the sample size N , representing the number of needles to account for, and the value of the R_{SL} parameter.
- 2)** Repeat N times:
 - 2.1)** Choose which ruler does access the export apparatus, determining the length of the i^{th} needle; the random choice is biased by the given value of R_{SL} , actually favoring one ruler with respect to the other.
 - 2.1.1)** If the short ruler $YscP_{388}$ is picked up, the length of the i^{th} needle is randomly chosen from a length population normally distributed around M_1 with a standard deviation SD_1 (from the experimental distribution obtained for short rulers in haploids).
 - 2.1.2)** If the Long ruler $YscP_{686}$ is picked up the length of the i^{th} needle is randomly chosen from a length population normally distributed around M_2 with a standard deviation SD_2 (from the experimental distribution obtained for long rulers in haploids).
 - 2.2)** Record the length of the i^{th} needle.
- 3)** The resulting nld is plotted in the histogram representation (bin size = 5 nm) and then analyzed with the EMA to find the best parameter of the Gaussian mixture model G2 (Equation S4)

By running the algorithm with $N = 1500$ (and $R_{SL} = 1$ (stating for and unbiased probability favoring neither the short nor the long ruler) a nld clearly featuring two peaks were obtained (Figure 2A in the main text). The EMA analysis of the obtained needle length population yielded the optimized variables for a Gaussian mixture model of the type G2 (Table S7) consistent with a neat bimodal normal distribution with unimodal components clearly matching the experimental distribution observed for the two kinds of haploids organisms. A cluster analysis of the length population showed an equal amount of needle belonging to the two peaks.

Mathematical algorithm for the dynamic model: Scenarios 2 and 3

The difference between the static and dynamic model for needle length regulation is in the number of ruler molecules employed (and thus secreted) during the growth of each needle. While in the static model a single ruler molecule is associated to the basal body and to the

needle during the whole growing phase, in the dynamic model, an indeterminate number of rulers pass through the needle, until a last one causes the substrate specificity switch and thus growth stop. Two different scenarios can be envisaged depending on the conditions required for the switch signaling to take place:

Scenario 2. The actual needle length L_n is greater (within a tolerance) than the length of the passing ruler L_r ; $L_n \geq L_r$

Scenario 3. The actual needle length L_n exactly matches (within a tolerance) the length of the passing ruler L_r ; $L_n \approx L_r$

As in the static model, in both scenarios of the dynamic model there is a competition between the two kinds of rulers in accessing the export apparatus to exert the regulatory function. Two global parameters, $[YscP_{388}]$ and $[YscP_{686}]$, and their ratio R_{SL} can be defined for the dynamic model as described above for the static one.

Since in the dynamic model, during needle growth, more than one ruler molecule is required to enter the basal body and get secreted, a certain degree of competition could be envisioned between needle subunits and ruler proteins in gaining access to the export apparatus. The average frequency of ruler admittance can be thus related to the ratio between the “needle subunit effective concentration” $[YscF]$ and the overall “ruler effective concentration” $[YscP]$ (Equations S6, S7).

$$R_{NR} = [YscF]/[YscP] = 1 / R_{NR}$$

Equation S7

The algorithm for generating the dynamic model nld on the basis of these assumptions is given in Scheme S2.

Scheme S2. Algorithm employed to obtain a nld according to the assumptions contained in the dynamic model (Scenarios 2 and 3).

- 1)** Input the sample size N , representing the number of needles to account for, the value of the R_{SL} and R_{RN} parameters, the stopping rule (Scenario 2 or 3).
- 2)** Repeat N times:
 - 2.1)** The actual needle length L_n is set to L_0 (unitary length of the needle subunit): $L_n = L_0$.
 - 2.2)** Choose whether a ruler or a needle subunit enters: the R_{RN} parameter is used to bias the random choice.
 - 2.2.1)** If a needle subunit enters, the actual needle length L_n is increased by L (the unitary contribution of a needle subunit): $L_n = L_n + L$.
 - 2.2.2)** If a ruler enters a choice is made between $Y_{scP_{388}}$ and $Y_{scP_{686}}$: the R_{SL} parameter is used to bias the random choice.
 - 2.2.2.1)** If the short ruler $Y_{scP_{388}}$ is picked up, the ruler length L_r is randomly chosen from a length population normally distributed around M_1 with a standard deviation SD_1 (from the experimental distribution obtained for short rulers in haploids).
 - 2.2.2.2)** If the long ruler $Y_{scP_{686}}$ is picked up the ruler length L_r is randomly chosen from a length population normally distributed around M_2 with a standard deviation SD_2 (from the experimental distribution obtained for short rulers in haploids).
 - 2.2.3)** Defining the stopping criterion:
 - 2.2.3.1)** If simulating Scenario 2: stop = YES if $L_n \geq L_r$
 - 2.2.3.2)** If simulating Scenario 3: stop = YES if $L_n \approx L_r$
 - 2.2.4)** Decide whether stop or not the growth process:
 - 2.2.4.1)** If stop \neq YES, the growing process continues: go to point **2.2**.
 - 2.2.4.2)** If stop = YES, the growing process stops: go to point **2.1**.
 - 2.3)** Record the length of the i^{th} needle and the number of rulers passed through the needle during its growth.
- 3)** The resulting nld is plotted in the histogram representation (bin size = 5 nm) and then analyzed with the EMA to find the best parameter of the Gaussian mixture model G2 (Equation S4)

Since there is no experimental evidence about the ruler frequency acceptance, the procedure described in Scheme 2 was repeated, for each of the two scenarios, setting different values of the $[Y_{scP}]$ parameter, thus obtaining 3D graphs by stacking together the histogram representation obtained at point 3 of the algorithm (in Figures S4, S5 selected histogram representation are reported, while in Figure S6 the 3D graphs and their 2D projection are given). To achieve a better understanding of the phenomenon the obtained values were plotted with respect $[Y_{scF}]/[Y_{scP}]$. The use of the reciprocal of the “effective ruler concentration” helped defining the lower boundary of the problem. Values of $[Y_{scF}]/[Y_{scP}]$ smaller than 1 implying the ruler being secreted with a greater frequency than the needle subunits themselves and resulting in a massive waste were not considered. For values of $[Y_{scF}]/[Y_{scP}]$ near 1 the system is “over-regulated”, since the length of the needle is “measured” by rulers with almost the same frequency as it is incremented by needle subunits. An increasing value of $[Y_{scF}]/[Y_{scP}]$ indicates a lower access frequency for the rulers, implying less frequent “measurements” of the needle length.

Scenario 2. When the “effective concentration” of rulers is similar to that of needle subunits ($[Y_{scF}]/[Y_{scP}] \approx 1$) the system is “over-regulated” by the smaller ruler which is able to meet the stopping criterion (actual needle length greater than the ruler length) before the longer one. This is evident in Figures S3A,C where a single peak (corresponding to the smaller needles) is present for low Y values.

As the value of $[Y_{scF}]/[Y_{scP}]$ increases the “measurement” frequency decreases, resulting in a broadening of the peak, also due to the more evident contributions to the nld by the long ruler.

For no value of $[Y_{scF}]/[Y_{scP}]$ within the considered range two distinct peaks were observed, as confirmed by the EMA analysis (Figure S7), accounting for a Gaussian mixture composed by two Gaussian functions whose centre is never further apart than 35 nm, well below the coalescence limit. The EMA analysis provides parameter values allowing for the G2 function to fit the nld with increasing success (decreasing error, Figure S7) for higher Y values but the computed likelihood decreases rapidly, indicating that the distribution fitted by the G2 function is neither bimodal nor normal. This is more evident by observing the nld computed for six representative values of $[Y_{scF}]/[Y_{scP}]$ (see Figure S4) and their respective Gaussian parameters, as computed by EMA (see Table S8).

Scenario 3. As seen for Scenario 2 when the effective ruler concentration is higher ($[Y_{scF}]/[Y_{scP}] \approx 1$) the system is “over-regulated” by the smaller ruler, and a single peak (corresponding to the smaller needles) is seen for low Y values (Figures S6B,D). As the value of $[Y_{scF}]/[Y_{scP}]$ increases and the “measurement” frequency decreases, two distinct peaks appeared in correspondence of the small and long needle, respectively. The EMA analysis provided insight to the nature of the obtained nld along the considered $[Y_{scP}]$ range. For values of $[Y_{scF}]/[Y_{scP}]$ above 40 the computed nld is clearly compatible with normal bimodal distribution, as confirmed by high likelihood and good fitting of the G2 function (small error). Below this threshold the computed distributions are unlikely to be either normal or bimodal. This was more evident by observing the nld computed for six representative values of $[Y_{scF}]/[Y_{scP}]$ (see Figure S5) and their respective Gaussian parameters, as computed by EMA (see Table S9).

Scenario 3, in contrast with Scenario 2, features an increasing number of “deregulated” needles for high Y values (low $[Y_{scP}]$). According to the employed algorithm, a needle was defined “deregulated” when its length exceeded 250 nm and its growth becomes unlikely to be interrupted. For Scenario 2, since the stopping rule imposes a stop when the needle length is greater than the passing by ruler, even needles allowed to grow over the threshold limit of 250 nm by a low “measurement” frequency (low $[Y_{scP}]$, high Y) could be stopped as soon as a ruler is allowed to enter the needle; thus the stopping probability is never null. In Scenario 3 the stopping rule is more restrictive, allowing for growth interruption only when the needle length is equal, within an arbitrary tolerance, to the passing-by ruler’s length. To be consistent with the method employed to choose the ruler length (point 2.2.2 of the algorithm reported in Scheme S2) the tolerance varies for each of the two rulers as a Gaussian function whose center and spread match the mean and the standard deviation of experimental distributions obtained for the two rulers in haploids (see Section S2). For this reason the probability of a needle to be stopped in its growth when its length exceeds the value of $M_2 + 3 \times SD_2$ is almost null. As the $[Y_{scP}]$ decreases (high Y values) the number of “deregulated” needles rapidly increases for Scenario 3, while for Scenario 2 an increasing number of simply exceedingly long needles are observed.

Statistical analysis of the experimental data obtained with diploid bacteria

The diploid nld was recorded for 8 different samples, obtaining for each one a set of rulers that was separately investigated by using the EMA method. The G2 parameters obtained for each set and for the overall ensemble are reported in Table S10. In each case the experimental nld is normal and bimodal, composed by two unimodal distribution closely resembling in both centre and spread the experimental distributions obtained for the two haploid organisms. A cluster analysis was made, based on the optimized Gaussian mixtures from EMA. The results of this analysis were employed to quantitatively classify the needles in two groups corresponding to the short and long species, respectively. It resulted that short

needle were predominant over the longer, the population of the former ones being about 60% of the total (Table S11). This result was consistent with those observed for mixture of haploids, and could be similarly attributed to a systematic error of the measure (see above).

Computational details

The algorithms described in the text were implemented using the “Python” programming language (van Rossum G. et al, 2001). The “matplotlib” graphics environment (van Rossum G et al, 2001) was used to generate histogram and line plots (Hunter J.D., 2007). The Gaussian mixture models were obtained by means of the “Python Mixture Model” implemented in the “PyMix” package (Georgi B. et al, 2010).

The “PyMix” package features an efficient version of the “Expectation-Maximization” Algorithm (EMA), an iterative method often used in statistics for finding maximum likelihood estimates of parameters in probabilistic models. This method consists in two steps iterated until convergence: 1) Expectation step, consisting in computing the expectation of the likelihood (often in logarithmic form) of the given distribution for some variables; 2) Maximization step, which optimize the parameters as to maximize the likelihood predicted at the previous step. In this context the term “likelihood” is not synonymous for “probability”: whereas the latter allows predicting unknown outcomes (probability distributions) from known parameters, the former is used to estimate unknown parameters on the basis of known outcomes (given distributions). In the present case the EMA was employed to find the best parameters of a Gaussian mixture model used to represent a bimodal normal distribution. The Gaussian mixture model with optimized parameters was then used to perform a cluster analysis on the given population.

The role of YscU in needle length control and substrate specificity switching

YscU recognizes translocators as export substrates of the *Yersinia* injectisome

Isabel Sorg¹, Stefanie Wagner¹, Marlise Amstutz¹, Shirley A Müller^{1,2}, Petr Broz¹,
Yvonne Lussi¹, Andreas Engel^{1,2} and Guy R Cornelis^{1,*}

¹ Biozentrum der Universität Basel, Basel, Switzerland.

² ME Müller Institute for Structural Biology, Basel, Switzerland.

Author contributions: I contributed to this paper by engineering the pSTW plasmids and analyzing their phenotype. I further contributed to the analysis of needle length of all strains presented in this paper.

YscU is an essential component of the export apparatus of the *Yersinia* injectisome. It consists of an N-terminal transmembrane domain and a long cytoplasmic C-terminal domain, which undergoes auto-cleavage at a NPTH site. Substitutions N263A and P264A prevented cleavage of YscU and abolished export of LcrV, YopB and YopD but not of Yop effectors. As a consequence, *yscU_{N263A}* mutant bacteria made needles without the LcrV tip complex and they could not form translocation pores. The graft of the export signal of the effector YopE, at the N-terminus of LcrV, restored LcrV export and assembly of the tip complex. Thus, YscU cleavage is required to acquire the conformation allowing recognition of translocators, which represent an individual category of substrates in the hierarchy of export. In addition, *yscU_{N263A}* mutant bacteria exported reduced amounts of the YscP ruler and made longer needles. Increasing YscP export resulted in needles with normal size, depending on the length of the ruler. Hence, the effect of the *yscU_{N263A}* mutation on needle length was the consequence of a reduced YscP export.

Introduction

The injectisome allows pathogenic or symbiotic bacteria to inject effector proteins across eukaryotic cell membranes, a process called type III secretion (T3S). It is evolutionary related to the bacterial flagellum (reviewed by Macnab (2003)). Both structures share a similar basal body consisting of several rings embedded in the two bacterial membranes connected by a central rod (Blocker *et al*, 1999, 2001; Marlovits *et al*, 2004; Morita-Ishihara *et al*, 2006). Depending on the family of injectisomes, a hollow stiff needle (Kubori *et al*, 1998, 2000; Blocker *et al*, 1999, 2001; Hoiczky and Blobel, 2001), a filament (Knutton *et al*, 1998; Daniell *et al*, 2001; Crepin *et al*, 2005) or a pilus (Van Gijsegem *et al*,

2000) terminate the structure. The length of the needle is genetically determined (Magdalena *et al*, 2002; Tamano *et al*, 2002; Journet *et al*, 2003).

The proximal rings are thought to contain the T3S export apparatus, made of a number of integral membrane proteins and soluble components (reviewed by Tampakaki *et al* (2004); Cornelis (2006); Galan and Wolf-Watz (2006)). In the *Yersinia* Ysc injectisome, a ca 60-nm long stiff hollow needle, assembled from the 9-kDa protein YscF, projects from the basal body into the exterior milieu (Hoiczky and Blobel, 2001). The needle terminates in a tip structure (the tip complex) made of the protein LcrV (Mueller *et al*, 2005). Upon contact with a eukaryotic cell membrane, the injectisome translocates a set of proteins called Yops (reviewed by Mota and Cornelis (2005)). These include the translocators (YopB and YopD) that form a pore in the target membrane and the effectors that traffic through this pore. The tip complex is thought to act as a scaffold for the folding and assembly of YopB and YopD into a functional pore (Goure *et al*, 2005).

During morphogenesis, the components of the transmembrane rings are handled by the Sec machinery, while those of the rod and the needle are sequentially exported by the T3S apparatus itself (Sukhan *et al*, 2001), traveling through the growing structure and polymerizing at its distal end (Li *et al*, 2002). There is no clear hierarchy in the synthesis of the components. Thus, the export apparatus is expected to switch its substrate specificity over time from early to late substrates, so that needle subunits (early substrates) are exported before LcrV and before the Yops (late substrates). This substrate specificity switch presumably leads to the arrest of needle growth, which determines the needle length. Hence, it is only triggered when the needle has reached its genetically defined length. The trigger is provided by YscP, another early substrate of the export apparatus. The N-terminal sequence of YscP is thought to act as a molecular ruler (Journet *et al*, 2003), while the C-terminal domain triggers the substrate specificity switch (Agrain *et al*, 2005a).

Mutations affecting FlhK, the flagellar YscP homolog, lead to extra-long hooks (called polyhooks) but no filament and hence bacteria are not motile (Hirano *et al*, 1994). Motile revertants appear as consequence of extragenic suppressive mutations in the integral membrane protein FlhB, suggesting that FlhB is involved in specificity switching (Kutsukake *et al*, 1994; Williams *et al*, 1996). FlhB has a long C-terminal cytosolic domain, which undergoes an autoproteolytic cleavage between N269 and P270; however, the resulting subdomains remain tightly associated with each other (Minamino and Macnab, 2000; Fraser *et al*, 2003; Ferris *et al*, 2005). This cleavage is abolished by the mutation N269A and cells producing FlhB_{N269A} assemble polyhook structures lacking filaments, leading to the proposal that cleavage and interaction of the two fragments generates conformational changes important for the specificity switching process (reviewed by Ferris and Minamino (2006)).

YscU and export substrate specificity

I Sorg *et al*

Figure 1 (A) Schematic representation of YscU based on studies by Allaoui *et al* (1994) and Lavander *et al* (2002). Letters indicate N-terminus (N), C-terminus (C), conserved NPTH motif (NPTH), transmembrane domain (TM, residues 1–210), N-terminal half of the cytoplasmic domain (CN, residues 211–263) and the C-terminal half of the cytoplasmic domain (CC, residues 264–354). Numbers indicate amino-acid positions in YscU from *Y. enterocolitica* W22703 (NCBI NC_002120). The black arrow represents the putative cleavage site at the NPTH motif. (B) Total membrane proteins of *Y. enterocolitica* E40 $\Delta yscU$ mutant bacteria, complemented *in trans* with wt or mutated alleles under the arabinose inducible pBAD promoter, were purified after 4 h of induction of the *yop* regulon and analyzed by immunoblot with anti-YscU antibodies. The different forms of YscU are indicated as follows: YscU (star), YscU_{TM+CN} (triangle), YscU_{CC} (circle), YscU_{TM+CN*} (hash) and YscU_{CC*} (cross). The latter two result from cleavage at the alternative site. (C) Total membrane proteins of the indicated *Y. enterocolitica* strains. Strains and plasmids used: wt (pYV40); $\Delta yscU$ (pLY4001); *yscU*_{N263A}, mutation inserted at the *yscU* locus (pISO4007); *yscU*⁺⁺ (pLY7); *yscU*_{N263A}⁺⁺⁺ (pSTW7); *yscU*_{P264A}⁺⁺⁺ (pSTW8); *yscU*_{T265A}⁺⁺⁺ (pSTW9).

The FlhB homolog in the *Yersinia* injectisome is YscU, a 354-residue polypeptide with four transmembrane helices and a long cytoplasmic tail (Allaoui *et al*, 1994) (Figure 1A). Like FlhB, YscU undergoes autoproteolytic cleavage before P264, generating a 10-kDa C-terminal fragment (Lavander *et al*, 2002). YscU_{N263A} is not cleaved at this site, but nevertheless retains the capacity to secrete Yops (Lavander *et al*, 2002).

The position of LcrV, at the tip of the needle, implies that LcrV is exported immediately after YscF but before the Yops. Thus, the hierarchy must consist of at least three categories of substrates and not two as in the flagellum; however, to date there are no genetic data to support this assumption. In this paper, we show that YscU_{N263A} is impaired in the export of the translocators LcrV, YopB and YopD but not in the export of the effector Yops. Accordingly, cells with YscU_{N263A} produce needles without tip complexes and this effect can be assigned to a lack of LcrV recognition. Thus, YscU is specifically involved in substrate recognition and has to be cleaved to acquire the conformation required for translocator recognition. This is the first genetic evidence that translocators

represent an individual category of substrates in the hierarchy of export. Accordingly, the translocators, and not the Yop effectors, occupy the same rank as flagellin in the assembly of the flagellum.

Results

Mutation of residue N263 or P264 changes the autocleavage properties of YscU

To analyze the phenotype of a non-cleavable YscU mutant, we generated different point mutations in the NPTH motif of YscU and overexpressed the resulting *yscU*_{N263A}, *yscU*_{P264A} and *yscU*_{T265A} genes *in trans* in *Y. enterocolitica* $\Delta yscU$ mutant bacteria. The *yscU*_{wt} gene and the mutated alleles were overexpressed from the pBAD promoter only at the end of the logarithmic growth phase when synthesis of the T3S system was induced by shifting to 37°C. In those conditions, we did not observe any clear toxicity of either the YscU_{wt} or the mutated YscU, as reported by others (Lavander *et al*, 2002). This discrepancy presumably results from differences in the experimental conditions used in the two reports. It is indeed likely that early overexpression of an integral membrane protein is toxic.

We then analyzed YscU in membranes purified from the different *Y. enterocolitica* strains incubated in secretion permissive conditions by immunoblotting with anti-YscU antibodies (Figure 1B). In strains expressing *yscU* or *yscU*_{T265A}, an YscU fragment of about 10 kDa was clearly detectable. This could be assigned to the C-terminal part (CC) after cleavage at or around the NPTH motif. In contrast no 10-kDa fragment was present in bacteria expressing *yscU*_{N263A} or *yscU*_{P264A}. Here, a protein fragment of about 16 kDa (indicated as CC*), probably resulting from cleavage at an alternative site, was observed, as already shown for an *yscU*_{ANPTH} mutant from *Y. pseudotuberculosis* (Lavander *et al*, 2002). This 16-kDa fragment was also present in lower amounts in membranes of strains expressing *yscU*_{wt} or *yscU*_{T265A}. The 24-kDa N-terminal part (TM+CN*) remaining after cleavage at this alternative site was detected in all YscU expressing strains. The cleavage at or around the NPTH motif, which results in the C-terminal 10-kDa (CC) fragment described above, would leave a 30-kDa N-terminal fragment (TM+CN). This 30-kDa fragment was not only found in strains overexpressing *yscU*_{wt} or *yscU*_{T265A} that contained the small 10-kDa fragment, but also in samples from bacteria overexpressing *yscU*_{N263A} or *yscU*_{P264A}, where we did not observe the 10-kDa fragment. Furthermore, uncleaved YscU_{wt} (TM+CN+CC) could be detected in all bacterial samples expressing *yscU*, demonstrating that cleavage was never complete. The data presented in Figure 1 are representative of a number of highly reproducible experiments.

Up to now, due to detection problems the cleavage of YscU and its flagellar homolog FlhB has only been demonstrated after overexpression of the protein (above and Minamino and Macnab, 2000; Lavander *et al*, 2002). We also analyzed the cleavage of wild-type (wt) amounts of YscU_{wt}. As shown in Figure 1C, the 10-kDa (CC) and the 30-kDa (TM+CN) fragments of YscU_{wt} could be detected in purified membranes. In addition, we observed cleavage at the alternative site, resulting in the 24-kDa (TM+CN*) and the 16-kDa (CC*) fragments, as shown for overproduced YscU_{wt} (Figure 1B, lane 2 and Figure 1C, lane 4). We then analyzed

a mutant expressing *yscU*_{N263A} from its native promoter on the virulence plasmid of *Y. enterocolitica*. In agreement with the data obtained after overproduction of YscU_{N263A}, a 30-kDa protein was present in the membranes from *yscU*_{N263A} mutant bacteria, suggesting cleavage at or around the NPTH motif, but again no 10-kDa fragment co-purified. In addition, the 24-kDa signal corresponding to the N-terminal part after cleavage at the alternative site was present. Importantly, the uncleaved YscU protein was always detected at 40 kDa (TM + CN + CC), demonstrating that even when expressed at natural levels, YscU cleavage was not complete. These data thus confirm the data obtained with the over-expressed protein presented above. Together, they suggest that YscU is cleaved at least at two different sites. Although the 10-kDa fragment only co-purifies with the remaining N-terminal part in strains producing YscU_{wt} or YscU_{T265A}, it does not formally rule out that the first cleavage occurs in YscU_{N263A} or YscU_{P264A}, because the sequence alteration could prevent the binding of the cleaved 10-kDa fragment. In contrast, the C-terminal 16-kDa fragment produced by the cleavage at the alternative site co-purifies with its N-terminal half, even in strains producing YscU_{N263A} or YscU_{P264A}. Although the data are not quantitative, they show that a preferred point of cleavage exists, which depends on the protein examined.

***yscU*_{N263A} and *yscU*_{P264A} mutants export effector Yops but no translocators**

Next we tested whether export of Yop proteins was affected in the different *yscU* mutants. To do this, the *yop* regulon was induced in the different *Y. enterocolitica* strains and the culture supernatants were analyzed by SDS-PAGE and Coomassie staining. In agreement with previously reported data, no Yops were secreted by Δ *yscP* and Δ *yscU* mutant bacteria (Allaoui *et al*, 1994; Stainier *et al*, 2000), and the *yscU*_{T265A} mutant showed the same pattern of exported proteins as the wt (Figure 2A). In contrast, the *yscU*_{N263A} and *yscU*_{P264A} mutant bacteria did not export translocators (Figure 2A). The defect in translocator export was not due to overexpression of *yscU*_{N263A}, since expression of *yscU*_{N263A} from its native promoter had the same effect (Figure 2A). Analysis of YopE and LcrV in culture supernatants by immunoblotting confirmed this result (Figure 2B). The intra-bacterial levels of YopE and LcrV were comparable in wt and *yscU*_{N263A} mutant bacteria. Whereas the export of YopE in *yscU*_{N263A} mutant bacteria was only slightly decreased compared to the wt, no exported LcrV could be detected (Figure 2B). To check whether overexpression of *lcrV* in an *yscU*_{N263A} mutant background could overcome the lack of export, as previously shown for export compromised *yscP* mutants (Agrain *et al*, 2005b), *lcrV* was overexpressed from the pBAD promoter by adding varying concentrations of L-arabinose (Figure 2C). Only on maximal *lcrV* overexpression with 0.5% L-arabinose a faint LcrV band could be observed in the supernatant fraction of *yscU*_{N263A} mutant bacteria (Figure 2C). Overexpression of *lcrV* in wt *Yersinia* did not change the export level, possibly because the export capacity of the wt was already saturated.

The *yscU*_{N263A} mutant does not assemble a tip complex and fails to induce lysis in red blood cells

The fact that the *yscU*_{N263A} mutant did not export the translocators LcrV, YopB and YopD suggests that this mutant may

Figure 2 Analysis of the Yop proteins secreted by different *yscU* mutants. (A) Coomassie-stained 12% SDS-PAGE of Yops secreted by wt, Δ *yscP*, Δ *yscU* mutant bacteria, Δ *yscU* mutant bacteria over-expressing mutated *yscU* alleles *in trans* from the pBAD promoter, or bacteria carrying the *yscU*_{N263A} allele at the *yscU* locus (natural *yscU* promoter). (B) Expression and export of LcrV and YopE in *Y. enterocolitica* E40 wt and *yscU*_{N263A} mutant bacteria. Total cell (TC) and supernatant fractions (SN) were analyzed by immunoblotting using anti-LcrV or anti-YopE antibodies. Shown are samples from two independent experiments. (C) Expression and export of LcrV after overexpression of *lcrV* *in trans* from the pBAD promoter in *Y. enterocolitica* wt and *yscU*_{N263A} mutant bacteria. L-arabinose concentrations ranging from 0.02 to 0.5% were used to induce LcrV synthesis when bacteria were shifted to 37°C and again 2 h later. TC and SN were analyzed by immunoblotting using anti-LcrV antibodies. Strains and plasmids used: wt (pYV40); Δ *yscP* (pLJ4036); Δ *yscU* (pLY4001); *yscU*⁺⁺⁺ (pLY7); *yscU*_{N263A}⁺⁺⁺ (pSTW7); *yscU*_{P264A}⁺⁺⁺ (pSTW8); *yscU*_{T265A}⁺⁺⁺ (pSTW9); *yscU*_{N263A} (pISO4007); *lcrV*⁺⁺⁺ (pPB42).

not be able to form the translocation pore. Formation of the translocation pore can be studied by infection of red blood cells (RBCs), which undergo hemolysis (Hakansson *et al*, 1996). Since *Y. enterocolitica* bacteria do not adhere to RBCs, a Δ *yopN* mutant that secretes Yops in a contact-independent manner has been used previously (Marenne *et al*, 2003).

Therefore, a Δ *yopN**yscU*_{N263A} mutant was generated. As expected from the Δ *yopN* deletion, secretion of Yops by the Δ *yopN**yscU*_{N263A} mutant was independent of the presence of calcium, whereas secretion of Yops by the *yscU*_{N263A} mutant and wt bacteria was calcium dependent (data not shown). The pattern of proteins secreted by the Δ *yopN**yscU*_{N263A} mutant was identical to that of proteins secreted by the *yscU*_{N263A} mutant, except that YopN was missing (Figure 3B). We analyzed the capacity of the Δ *yopN**yscU*_{N263A} mutant to

YscU and export substrate specificity

I Sorg *et al*

Figure 3 The *yscU*_{N263A} mutant does not induce hemolysis in RBC due to a missing tip complex. (A) Transmission electron micrographs of *Y. enterocolitica* E40 WT, $\Delta yopN$ and $\Delta yopN yscU_{N263A}$ bacteria negatively stained with 2% uranyl acetate. Scale bar, 100 nm. Needles are indicated by arrowheads. (B) Yops secreted by *Y. enterocolitica* wt, $\Delta yopN$, *yscU*_{N263A} and $\Delta yopN yscU_{N263A}$ bacteria. Coomassie-stained 12% SDS-PAGE. The position of YopN is indicated on the left. (C) Percentage lysis of RBCs after 1 h of contact with the indicated *Y. enterocolitica* strains. (D) STEM dark-field image of *Y. enterocolitica* *yscU*_{N263A} needles. Protein is displayed in bright shades. Inset: wt needles similarly imaged. The *yscU*_{N263A} mutant needles had rather pointed ends (asterisk); the tip complexes so characteristic of wt needles (arrowhead) were not detected. Scale bar, 20 nm. Strains: wt (pYV40); $\Delta yopN$ (pIM41); $\Delta yopN yscU_{N263A}$ (pISO4010); *yscU*_{N263A} (pISO4007); $\Delta HOPEMNV$ (pMN4002).

induce lysis in RBCs. In agreement with the loss of translocator export, lytic activity was neither observed for the $\Delta yopN yscU_{N263A}$ mutant nor for the negative control $\Delta HOPEMNV$ mutant lacking LcrV (Figure 3C). Like for wt, and $\Delta yopN$ mutant bacteria, needles could be observed on the surface of $\Delta yopN yscU_{N263A}$ mutant bacteria (Figure 3A). The needles from *yscU*_{N263A} mutant bacteria were purified and analyzed by scanning transmission electron microscopy (STEM) (Figure 3D). Out of 51 needles analyzed, none had a tip and 16 had a clear pointed end (Figure 3D), as previously reported for the *lcrV* mutant (Mueller *et al*, 2005). These data confirm the defect in the export of LcrV.

The impaired export of LcrV is due to a lack of recognition by the YscU_{N263A} protein

There might be at least two reasons why LcrV is not exported in the *yscU*_{N263A} mutant; either LcrV is not recognized by the YscU_{N263A} protein or the YscU_{N263A} protein has an altered conformation, which blocks the export channel for some substrates. To investigate if the channel is still permissive for LcrV, we fused the export signal of the effector YopE to the N-terminus of LcrV and analyzed the export of the hybrid protein in the *yscU*_{N263A} mutant. As shown in Figure 4A, a protein of the expected size was detected by Coomassie-stained SDS-PAGE of the supernatant fraction. The identity

Figure 4 YopE₁₋₁₅LcrV is exported by *Y. enterocolitica yscU*_{N263A} mutant bacteria and forms a tip complex. (A) Yops secreted by *Y. enterocolitica* E40 wt (pYV40) and *Y. enterocolitica* E40 *yscU*_{N263A} (pISO4007) mutant bacteria overexpressing *lcrV* (pPB42) or *yopE*₁₋₁₅*lcrV* (pISOA132) *in trans* from the pBAD promoter. The position of the YopE₁₋₁₅LcrV protein is indicated by the arrowhead. (B) Total cell (TC) and supernatant fractions (SN) of the same cultures as in (A) were analyzed by immunoblot with anti-LcrV antibodies. (C) Lysis of RBCs after 1 h of contact with the indicated *Y. enterocolitica* E40 strains. (D) STEM images of needles isolated from *Yersinia yscU*_{N263A} expressing YopE₁₋₁₅LcrV from the pBAD promoter. Protein is displayed in bright shades. Scale bar, 20 nm. Strains and plasmids: wt (pYV40); *yscU*_{N263A} (pISO4007); Δ HOPEMN (pIM417); Δ HOPEMN (pMN4002); Δ yopN *yscU*_{N263A} (pISO4010); *lcrV*⁺⁺⁺ (pPB42); *yopE*₁₋₁₅*lcrV*⁺⁺⁺ (pISOA132).

of the protein was confirmed by immunoblot using anti-LcrV antibodies (Figure 4B). In contrast to the YopE-hybrid protein, LcrV alone was not exported in the *yscU*_{N263A} mutant. These data suggest that the loss of LcrV export in the *yscU*_{N263A} mutant is not due to changes of the channel properties, but rather due to a defect in recognition of LcrV as export substrate. We then wondered whether the YopE₁₋₁₅LcrV hybrid protein would be functional in the *yscU*_{N263A} mutant, that is, whether this protein would be able to form a functional tip complex. We first investigated the functionality of the hybrid protein in an *lcrV* mutant (here Δ HOPEMN), by testing its ability to induce lysis of RBCs. The multi-effector mutant Δ HOPEMN was used as positive control and induced 46% hemolysis, whereas the *lcrV* mutant Δ HOPEMN only led to 1% hemolysis (Figure 4C). Overexpression of either *lcrV* or *yopE*₁₋₁₅*lcrV* in *lcrV* mutant bacteria could restore hemolysis up to wt level, indicating that the hybrid protein was functional (Figure 4C). As expected, expression of *yopE*₁₋₁₅*lcrV* in the Δ yopN *yscU*_{N263A} mutant could not restore the lytic activity, because not only LcrV but also the two other translocators YopB and YopD were not exported by this mutant (Figure 4C). When purified needles of an *yscU*_{N263A} mutant expressing *yopE*₁₋₁₅*lcrV* were analyzed using STEM, tip complexes were detected on 43 out of 76 analyzed needles (Figure 4D). This shows that LcrV export by *yscU*_{N263A} mutant bacteria could be restored by using the export signal of YopE. Furthermore, the *yopE*₁₋₁₅*lcrV* fusion resulted in a functional protein that was able to form a tip complex. From these data we cannot say that not all the

needles have a tip, because we can never exclude that some needles analyzed broke during purification.

Needles of *Yersinia yscU*_{N263A} and *yscU*_{P264A} mutants are longer and less regulated

Next, we were interested in whether the different *yscU* mutations described above would affect the length of the injectosome needle. Therefore, needles from *Y. enterocolitica* Δ *yscU* bacteria overexpressing *yscU*, *yscU*_{N263A}, *yscU*_{P264A} or *yscU*_{T265A} were measured. Needles of *yscU*_{T265A} mutant bacteria had wt length (*yscU*_{wt}: median 61 ± 15 nm; *yscU*_{T265A}: median 63 ± 15 nm), whereas needles from bacteria overexpressing *yscU*_{N263A} or *yscU*_{P264A} were longer and less controlled than the wt (*yscU*_{N263A}: median 107 ± 51 nm; *yscU*_{P264A}: median 119 ± 53 nm) (Supplementary Figure S1). These data reflect the differences that we reported above for the cleavage of YscU and the export of the translocators.

Needle length in a *yscU*_{N263A} mutant is still controlled by YscP

To analyze whether YscP still exerts its ruler function in a *yscU*_{N263A} mutant, we combined *yscP* alleles of different sizes with the *yscU*_{N263A} allele. As shown before (Journet *et al*, 2003; Mota *et al*, 2005), *yscU*_{wt} bacteria producing the 388-amino acid ruler YscP₃₈₈ made shorter needles (49 ± 7 nm), whereas bacteria producing the 680-amino acid ruler YscP₆₈₀ made longer needles (149 ± 45 nm) than *yscU*_{wt} bacteria endowed with the wt ruler YscP₅₁₅ (67 ± 11 nm) (Figure 5A, histograms I–III).

YscU and export substrate specificity I Sorg *et al*

Figure 5 (A) Histograms showing the length of needles from *Y. enterocolitica* E40 *yscU_{wt}* and E40 *yscU_{N263A}* mutant bacteria expressing three different YscP proteins either from their native promoter (histograms I–VI) or additionally *in trans* from the pBAD promoter (histograms VII–XII). Overexpression of *yscP* *in trans* from the pBAD promoter was induced with 0.1% L-arabinose. N, number of needles measured; s.d., standard deviation. (B) The supernatant (SN) of culture of *Y. enterocolitica* E40 strains expressing the three indicated *yscP* alleles from their native promoter in an *yscU_{N263A}* mutant background were analyzed by immunoblot with anti-YscP antibodies. (C) Total cell (TC) and supernatant fractions (SN) of *Y. enterocolitica* *yscU_{wt}* and *yscU_{N263A}* mutant bacteria expressing the indicated *yscP* alleles from their native promoter and additionally *in trans* from the pBAD promoter. Overexpression of *yscP* alleles from the pBAD promoter was induced with 0.1% L-arabinose. Samples were analyzed by immunoblotting using anti-YscP antibodies. (D) Plot of the needle length versus the number of residues in YscP for *Y. enterocolitica* strains expressing different *yscP* alleles from their native promoter in either *yscU_{wt}* or *yscU_{N263A}* mutant bacteria. The medians and s.d.s of histograms I–VI that are given in (A) are shown. (E) Plot of the needle length versus the number of residues in YscP for *Y. enterocolitica* *yscU_{wt}* and *yscU_{N263A}* mutant bacteria expressing indicated *yscP* alleles from their native promoter and additionally *in trans* from the pBAD promoter, which was induced with 0.1% L-arabinose. The medians and s.d.s of histograms VII–XII that are given in (A) are shown. Strains and plasmids used: wt (pYV40); *yscP₃₈₈* (pLJ4022); *yscP₅₁₅* (pYV40); *yscP₆₈₀* (pLJM4001); *yscU_{N263A}yscP₃₈₈* (pISO4011); *yscU_{N263A}yscP₅₁₅* (pISO4007); *yscU_{N263A}yscP₆₈₀* (pISO4012); *yscU_{N263A}* and *yscP₃₈₈⁺⁺⁺* (pISO4011 + pCA20); *yscU_{N263A}* and *yscP₅₁₅⁺⁺⁺* (pISO4007 + pLJ6); *yscU_{N263A}* and *yscP₆₈₀⁺⁺⁺* (pISO4012 + pLJ19); *yscU_{wt}* and *yscP₃₈₈⁺⁺⁺* (pLJ4022 + pCA20); *yscU_{wt}* and *yscP₅₁₅⁺⁺⁺* (pYV40 + pLJ6); *yscU_{wt}* and *yscP₆₈₀⁺⁺⁺* (pLJM4001 + pLJ19).

yscU_{N263A} mutant bacteria producing the different YscP proteins made longer needles than *yscU_{wt}* bacteria. Length still correlated with the number of residues of YscP, but the control was not as tight, as shown by the larger standard deviations (*yscU_{N263A}yscP₃₈₈*: 91 nm ± 63 nm; *yscU_{N263A}yscP₅₁₅*: 111 ± 43 nm; *yscU_{N263A}yscP₆₈₀*: 222 ± 96 nm) (Figure 5A, histograms IV–VI). By plotting the medians of needle length against the number of amino acids in YscP, we obtained parallel slopes for the *yscU_{wt}* and the *yscU_{N263A}* mutant (Figure 5D). In addition to these changes in needle length, *yscU_{N263A}* mutant bacteria exported less YscP than wt bacteria (Figure 5B and C). The increase in needle length as well as the decrease in length control could be due to this decrease in YscP export, as shown previously (Agrain *et al*, 2005b). We therefore tested whether an increase in YscP production would compensate the defects in length control.

Therefore, *yscP₃₈₈*, *yscP₅₁₅* and *yscP₆₈₀* were overexpressed from the pBAD promoter in *yscU_{N263A}* mutant bacteria harboring the corresponding *yscP* allele on the virulence plasmid. Overproduction of the different YscP proteins increased their export to wt level, as shown by immunoblot analysis of the total cell and supernatant fractions using anti-YscP antibodies (Figure 5C). Increased production of YscP₃₈₈, YscP₅₁₅ and YscP₆₈₀ in *yscU_{N263A}* mutant bacteria (Figure 5A, histograms VII–IX) led to needles that were comparable to those of the corresponding *yscU_{wt}* strains (Figure 5A, histograms X–XII). Although *yscU_{N263A}* mutant bacteria overexpressing *yscP* had needles of the expected length (Figure 5A, histogram VIII), they still did not export translocators (Supplementary Figure S2).

The plot in Figure 5E shows that overexpression of YscP can indeed restore needle length control in the *yscU_{N263A}*

mutant to wt level. This showed that the defect in needle length control of the *yscU*_{N263A} mutant was rather due to a failure in YscP export than to a failure of the substrate specificity switch.

Discussion

The fact that the injectisome exports its own distal components, before it exports the effectors, implies that the T3S apparatus can recognize and sequentially export different categories of substrates. To achieve this, it is believed to switch its substrate specificity when assembly is completed.

To better understand this sequential export process, we introduced mutations into the NPTH cleavage site of YscU and analyzed the phenotypes. At variance with previous reports on FlhB (Minamino and Macnab, 2000) and YscU (Lavander *et al*, 2002), we not only analyzed the phenotype after overexpression of cloned *yscU* alleles, but also after replacement of the *yscU* alleles on the pYV plasmid, ensuring physiological expression levels. To detect minute protein quantities, we probed the proteins with an anti-YscU antiserum rather than an antibody directed against the C-terminus or a C-terminal His-tag. Our results confirmed that the 40-kDa YscU is naturally cleaved into a TM + CN 30-kDa fragment and a 10-kDa CC fragment, as shown previously for FlhB (Minamino and Macnab, 2000) and for YscU from *Y. pseudotuberculosis* (Lavander *et al*, 2002). In good agreement with the estimated stoichiometry of two FlhB molecules per flagellum (Zhu *et al*, 2002), unless overexpressed, the CC product from YscU could only be detected after enrichment by purification of the membrane fraction from *Y. enterocolitica*. Surprisingly, the cleavage of YscU was never complete, even at physiological expression levels, although bacteria were harvested at a stage where all the needles analyzed had their normal length and tip complex. No CC fragment was detected for the mutant proteins YscU_{N269A} and YscU_{P264A}, as shown before by Lavander *et al* (2003) using C-terminal tagged YscU. As pointed out by these authors, this suggests that cleavage did not occur. However, since a band corresponding to the size of the TM + CN fragment was still observed, we cannot formally rule out that cleavage was prevented. We observed an alternative cleavage site in the YscU_{N269A} and YscU_{P264A} mutant proteins, yielding a *ca* 24-kDa (TM + CN*) and a *ca* 16-kDa (CC*) fragment. This alternative cleavage of YscU is reminiscent of the alternative cleavage observed in FlhB_{N269A} and FlhB_{P270A}, but was not reported for YscU from *Y. pseudotuberculosis*. Surprisingly, we detected the TM + CN* fragment in extracts from bacteria producing YscU_{wt}, suggesting that even YscU_{wt} could be partially cleaved at this alternative cleavage site.

The *yscU*_{N263A} mutant bacteria assembled injectisome needles, but their length seemed to be poorly controlled and the median length was 111 nm rather than the 67 nm found for wt bacteria. When this *yscU*_{N263A} allele was combined with a longer (680 codons) and a shorter (388 codons) allele of *yscP*, the median needle lengths were 222 nm and 91 nm, respectively, indicating that needle length was still dependent on the length of the YscP ruler, although the standard deviation was much larger. In addition to this loose length control, the *yscU*_{N263A} bacteria released less YscP into the culture supernatant than wt bacteria do, although the intra-bacterial amount of protein was un-

changed. We tried to overcome the poor export efficiency of YscP by overexpressing the gene downstream from the pBAD promoter. As expected from the previous work of Agrain *et al* (2005b), overexpression of the three different *yscP* alleles indeed led to the export of more YscP proteins, and also to a better control of needle length. The latter was in fact as good as in *yscU*_{wt} bacteria. Hence, we conclude that the *yscU*_{N263A} mutation reduces the efficacy of the T3S system to export YscP, which, indirectly, leads to a less stringent control of needle length. We also conclude that the *yscU*_{N263A} mutation does not affect the capacity of the T3S export apparatus to switch off the export of the YscF needle subunits when the needle reaches its genetically defined length.

These data demonstrate that the cleavage at the NPTH motif is not required to switch off needle subunit export. Even more, they confirm that the same variants of YscU and YscP can give rise to two different needle lengths, depending on the amount of YscP exported. To us, this rules out the hypothesis that YscU could play a role as a timer to determine needle length, as was proposed for the flagellar hook length control (Moriya *et al*, 2006).

*yscU*_{N263A} mutant bacteria also released slightly less effector Yops than wt bacteria, but the export of effectors was still significant. This observation shows that the export machine is still capable of switching on the export of Yops. Hence, the *yscU*_{N263A} mutation does not affect the substrate specificity switching from early (YscF, YscP) to late (Yops) substrates. This interpretation agrees with the observations reported by Lavander *et al* (2002) that mutation *yscU*_{N263A} does not affect Yop secretion in *Y. pseudotuberculosis*. However, it may seem at odds with the observation that mutation *flhB*_{N269A} prevents export of flagellin, and with the interpretation that it inhibits the substrate specificity switch.

The most intriguing phenotype of the *yscU*_{N263A} mutation was the deficiency in export of the translocators LcrV, YopB and YopD. In good agreement with the fact that LcrV was not exported, needles produced by the mutant bacteria had no tip complex.

A deficiency in translocator export is not completely unprecedented. The *invE* mutant of *Salmonella enterica* showed reduced secretion of the translocators SipB, SipC and SipD, while the export of other T3S effectors was increased (Kubori and Galan, 2002). Beside these observations and the fact that InvE is not required for the assembly of the needle complex, nothing is known about the actual function of InvE and its putative homologs. Mutants *sepL* and *sepD*, mutants of enteropathogenic and enterohemorrhagic *Escherichia coli*, as well as of *Citrobacter rodentium*, have a similar phenotype; translocator secretion is completely abolished, while the export of effector proteins is increased (Deng *et al*, 2005). It was suggested that SepL and SepD are not only necessary for efficient translocator secretion but also control a switch from translocator to effector secretion by sensing certain environmental signals such as low calcium (Deng *et al*, 2005). A *yscW* (called earlier *virG*) mutant of *Y. enterocolitica* also shows a decrease in the amounts of secreted proteins, especially of the translocators YopB, YopD and LcrV (Allaoui *et al*, 1995). YscW is the pilot protein of the secretin YscC (Burghout *et al*, 2004) and hence its absence probably modifies the channel properties.

Here, the failure to export LcrV and to assemble the needle tip could be circumvented by the N-terminal addition of the

YscU and export substrate specificity I Sory *et al*

YopE export signal to LcrV. This indicates that the failure to export LcrV was not due to a change in the channel conformation, making it unsuitable for protein export, but rather to a failure in substrate recognition. This implies that the translocators have a specific type of export signal and a status distinct from the effectors regarding export. This makes sense, since they need to be exported before the effectors (Cornelis and Wolf-Watz, 1997). We already know that LcrV is exported before the Yops, since it forms the tip complex, even in the absence of Yop secretion (Mueller *et al*, 2005). However, no mutation specifically affecting export of the effectors has been described before. Surprisingly, while considerable effort was made to unravel the export signal of YopE (Michiels and Cornelis, 1991; Sory *et al*, 1995; Anderson and Schneewind, 1997), YopH (Michiels and Cornelis, 1991; Sory *et al*, 1995), YopN (Anderson and Schneewind, 1997) and YopQ (Michiels and Cornelis, 1991; Anderson and Schneewind, 1999) in *Yersinia*, little has been done to decipher the signal of translocators. It is known that LcrV can be exported even with an N-terminal His-tag, and that both the N- and C-termini of LcrV are required for its export (Fields *et al*, 1999). This can be taken as a hint that the signals are different for effectors and translocators, although more work is needed to characterize the export signals of the translocators and hence to understand the hierarchy of assembly. The export signal of YscP, an early substrate, was recently characterized and turned out to be totally different from the known export signal of effectors (Agrain *et al*, 2005b).

As mentioned above, the phenotype of the *yscU*_{N263A} mutation may appear, at first sight, to be different from the phenotype of the *flhB*_{N269A} mutation, in the sense that YscU_{N263A} allows Yop (late substrate) export, while FlhB_{N269A} does not allow flagellin export. However, the two observations can easily be reconciled, given the additional observation that YscU_{N263A} prevents export of the translocators. Keeping in mind that there are two hierarchy classes in the assembly of the flagellum (hook/rod and filament) and three hierarchy classes in the operation of the injectisome (needle, translocators, effectors), both mutants are simply deficient in the export of the second hierarchy class.

Finally, our results confirm that YscU, and especially the structure of the CC fragment, plays a critical role in substrate recognition. They also show that the translocators are specifically recognized by YscU and thus, the injectisome has at least three classes of substrates. However, they do not provide any evidence that cleavage of the CC fragment is involved in the substrate specificity switch.

Materials and methods

Bacterial strains, plasmids and genetic constructions are listed in Supplementary Table 1.

Alleles to be inserted in the pYV plasmids were subcloned into the pKNG101 suicide vector and the allelic exchange was selected by plating diploid bacteria on sucrose (Kaniga *et al*, 1991).

E. coli Top10 was used for plasmid purification and cloning. *E. coli* BL21 Rosetta was used for protein expression. Bacteria were routinely grown on Luria-Bertani agar plates and in liquid Luria-Bertani medium. Ampicillin was used at a concentration of 200 µg/ml to select for expression vectors.

Plasmids were generated using either *Pfu* turbo polymerase (Stratagene) or Vent DNA polymerase (New England Biolabs). The oligonucleotides used for genetic constructions are listed in Supplementary Table 2. All constructs were confirmed by sequencing using a 3100-Avant genetic analyzer (ABI Prism).

Yop secretion

Induction of the *yop* regulon was described by Cornelis *et al* (1987). Expression of the different genes cloned downstream from the pBAD promoter was routinely induced by adding 0.2% L-arabinose to the culture just before the shift to 37°C, and again 2 h later. The carbon source was glycerol (4 mg/ml) when expressing genes from the pBAD promoter, and glucose (4 mg/ml) in the other case. Total cell and supernatant fractions were separated by centrifugation at 20 800 g for 10 min at 4°C. The cell pellet was taken as total cell fraction. Proteins in the supernatant were precipitated with trichloroacetic acid 10% (w/v) final for 1 h at 4°C.

Secreted proteins were analyzed by Coomassie-stained 12% SDS-PAGE; in each case, proteins secreted by 3×10^8 bacteria were loaded per lane. For detection of YscP in total cells, 1.6×10^8 bacteria were loaded per lane. For YscP detection in supernatants, the supernatants from 2.5×10^7 bacteria were loaded per lane. For analysis of LcrV and YopE, 2.5×10^7 bacteria and the supernatants from 2×10^7 bacteria were loaded per lane on a 12% SDS-PAGE. Immunoblotting was carried out using rabbit polyclonal antibodies against LcrV (MIPA220; 1:2000) and YscP (MIPA57; 1:3000), or rat polyclonal antibodies against YopE (MIPA94; 1:10000). Detection was performed with the respective secondary antibodies conjugated to horseradish peroxidase (1:5000; Dako), before development with supersignal chemiluminescent substrate (Pierce).

Electron microscopy

Needles at the cell surface of bacteria were visualized by transmission electron microscopy, as described by Hoiczky and Blobel (2001) and Agrain *et al* (2005b). After 4 h of induction of the *yop* regulon at 37°C, bacteria were harvested at 2000 g and resuspended gently in 20 mM Tris-HCl, pH 7.5. Droplets were applied for 1 min to freshly glow-discharged, formvar-carbon-coated grids, and negatively stained with 2% (w/v) uranyl acetate. Bacteria were visualized in a Philips CM100 electron microscope at a nominal magnification of $\times 20\,000$ and an acceleration voltage of 80 kV. Sizes were measured with the 'Soft imaging system' software (Hamburg, Germany).

Needle purification

Needles were purified from *Y. enterocolitica* cultures incubated under secretion permissive conditions. Bacteria from 300 ml culture were harvested by centrifugation (10 min at 5700 g) and washed once with 20 mM Tris-HCl, pH 7.5 (1/30 of initial culture volume). The washing supernatant was passed through a 0.45 µm mesh filter (cellulose acetate membrane) and then centrifuged for 30 min at 20 000 g. The resulting pellet was resuspended in 20 mM Tris-HCl, pH 7.5 (1/3000 of initial culture volume) and analyzed by electron microscopy (Mueller *et al*, 2005).

STEM

The purified needles were diluted with buffer (20 mM Tris-HCl, pH 7.5), as required, adsorbed to thin carbon film, washed with four droplets of quartz double-distilled water and stained with 2% (w/v) sodium phosphotungstate. Digital dark-field images were generated using a Vacuum Generators HB5 STEM interfaced to a modular computer system (Tietz Video and Image Processing Systems GmbH, D-8035 Gauting). The microscope was operated at 100 kV and a nominal magnification of $\times 500\,000$, using doses that ranged between 4400 and 13 500 electrons/nm².

Hemolysis

Hemolytic assays were carried out as described by Goure *et al* (2005).

Purification of total membrane proteins

To purify total cell membranes, *Yersinia* bacteria were cultivated in secretion permissive conditions (BHI-Ox), as described before. Bacteria from 200 ml culture were harvested by centrifugation (20 min/5000 g/4°C) and washed once with phosphate-buffered saline (PBS). After resuspending the cells in 5 ml buffer I (50 mM Hepes pH 7.6, 500 mM potassium acetate, 5 mM magnesium acetate) containing the protease inhibitor cocktail complete Mini (Roche), 0.7 mg/ml lysozyme was added, followed by a 30-min incubation at 4°C. Then cells were lysed by sonication on ice. After removal of unbroken cells by low-speed centrifugation (30 min/6000 g/4°C), the supernatant was passed through a 0.45 µm mesh filter (cellulose acetate membrane) and centrifuged at high speed

(2 h/150 000 g/4°C). The pellet containing the total cell membranes was resuspended in 400 µl buffer I. Lipids were extracted with 400 µl *n*-hexan for 30 min/4°C on a rotating wheel. After isolation of the lower hydrophilic phase, proteins were precipitated by addition of four volumes acetone (1 h/4°C), centrifuged (10 min/20–800 g/4°C) and resuspended in 160 µl buffer II (7 M urea, 2 M thiourea, 2% CHAPS), and supplemented with 40 µl 5 × SDS loading buffer (5 × SDS loading buffer: 225 mM Tris-HCl, pH 6.8, 5% SDS, 50% glycerol, 50 mM DTT, bromophenol blue). Samples were separated on a 15% SDS-PAGE, transferred onto nitrocellulose membrane and analyzed by immunoblotting with anti-YscU antibodies.

YscU antibodies

To produce polyclonal anti-YscU antibodies (MIPA 221), YscU_{211–354} was expressed from the pBAD promoter with a C-terminal His-tag, using plasmid pLY1. A soluble His-protein was produced in *E. coli* Top10 and purified on chelating sepharose beads (Amersham

Biosciences). A rabbit was immunized by four injections with a total of 1 mg of YscU_{211–354} (CER, Marloie, Belgium). For immunoblot analysis, anti-YscU antibodies were used at a dilution of 1:1000.

Supplementary data

Supplementary data are available at *The EMBO Journal* Online (<http://www.embojournal.org>).

3 **Needles of *Y. enterocolitica* *yscU*_{N263A} and *yscU*_{P264A} mutants are longer**
 4 **and less regulated**

5 To analyze the influence of mutations in the NPTH motif of YscU on needle
 6 length, *yscU*_{wt}, *yscU*_{N263A}, *yscU*_{P264A}, or *yscU*_{T265A} were overexpressed from the
 7 pBAD promoter in *Y. enterocolitica* E40 Δ *yscU* mutant bacteria. Needles were
 8 analyzed after 4 hour induction of the *yop* regulon at 37 °C. The pBAD
 9 promoter was induced by adding 0.2 % L-arabinose to the culture just before
 10 the shift to 37 °C, and again 2 hours later. Bacteria were harvested at 2000 *g*
 11 and resuspended gently in 20 mM Tris-HCl, pH 7.5. Droplets were applied for
 12 1 minute to freshly glow-discharged, formvar-carbon coated grids, and
 13 negatively stained with 2 % (w/v) uranyl acetate. Bacteria were visualized in a
 14 Philips CM100 transmission electron microscope at a nominal magnification of
 15 20 000x and an acceleration voltage of 80 kV. Sizes were measured with the
 16 'Soft imaging system' software (Hamburg, Germany).

17

Legend to Figure S1

Histograms showing the needle length of *Y. enterocolitica* E40 $\Delta yscU$ mutant bacteria (pLY4001) overexpressing *yscU* (pLY7), *yscU*_{N263A} (pSTW7), *yscU*_{P264A} (pSTW8), or *yscU*_{T265A} (pSTW9). N, number of measured needles; sd, standard deviation.

1 **Supplementary data 2**

2 **Overexpression of *yscP* in the *Y. enterocolitica yscU_{N263A}* mutant**
 3 **background does not restore translocator export**

4 Needles of *Y. enterocolitica yscU_{N263A}* mutant bacteria were longer and less
 5 regulated than needles from wildtype bacteria. The same was true for
 6 *yscU_{N263A}* mutant bacteria producing a shorter (YscP₃₈₈) or a longer (YscP₆₈₀)
 7 version of the molecular ruler YscP. Although *yscP₃₈₈* led to shorter and
 8 *yscP₆₈₀* to longer needles than the wildtype *yscP₅₁₅* ruler, needles were longer
 9 and less regulated than needles from the corresponding *yscU* wildtype strain.
 10 Overexpression of different *yscP* alleles in *yscU_{N263A}* mutant bacteria led to
 11 needles that were comparable to those of the corresponding *yscU* wildtype
 12 strains. Although *yscU_{N263A}* mutant bacteria overexpressing *yscP* had needles
 13 with the expected length, they still did not export the translocators YopB,
 14 YopD, and LcrV (Figure S2).

15

16 **Legend to Figure S2**

17 Coomassie-stained 12 % SDS-PAGE showing the Yops secreted by *Yersinia*
 18 *yscU_{wt}* and *yscU_{N263A}* mutant bacteria producing the indicated YscP proteins
 19 from their native promoter and additionally from the pBAD promoter.
 20 Overexpression of YscP proteins from the pBAD promoter was induced with
 21 0.1 % L-arabinose. *Yersinia* wildtype (WT) *yscU_{N263A}* mutant strains were used
 22 as controls. The secreted Yops are indicated on the side. Yop translocators
 23 are shown in bold and Yop effectors in regular letters.

Author contributions: I contributed to this paper by engineering the pSTW plasmids, analyzing the needle length and export levels of YscP of all YscU mutants presented in this paper.

The inner-membrane protein YscU has an important role during the assembly of the *Yersinia enterocolitica* type III secretion injectisome. Its cytoplasmic domain (YscU^C) recognizes translocators as individual substrates in the export hierarchy. Activation of YscU entails auto-cleavage at a conserved NPTH motif. Modification of this motif markedly changes the properties of YscU, including translocator export cessation and production of longer injectisome needles. We determined the crystal structures of the uncleaved variants N263A and N263D of YscU^C at 2.05 Å and 1.55 Å resolution, respectively. The globular domain is found to consist of a central, mixed β -sheet surrounded by α -helices. The NPTH motif forms a type II β -turn connecting two β -strands. NMR analysis of cleaved and uncleaved YscU^C indicates that the global structure of the protein is retained in cleaved YscU^C. The structure of YscU^C variant N263D reveals that wild type YscU^C is poised for cleavage due to an optimal reaction geometry for nucleophilic attack of the scissile bond by the side chain of Asn263. *In vivo* analysis of N263Q and H266A/R314A YscU variants showed a phenotype that combines the absence of translocator secretion with normal needle-length control. Comparing the structure of YscU to those of related proteins reveals that the linker domain between the N-terminal transmembrane domain and the auto-cleavage domain can switch from an extended to a largely α -helical conformation, allowing for optimal positioning of the auto-cleavage domain during injectisome assembly.

Edited by R. Huber

Introduction

The enteric pathogen *Yersinia enterocolitica* uses a sophisticated injection machinery called an injectisome to translocate effector proteins across eukaryotic cell membranes by type III secretion (T3S). This supramolecular structure, found in many Gram-negative pathogenic or symbiotic bacteria, including *Salmonella* spp., *Shigella* spp. and enteropathogenic *Escherichia coli*, is evolutionarily related to the bac-

terial flagellum.¹ A basal body consisting of several rings connected by a central rod spans the two bacterial membranes in both structures.^{2–5} The basal body bears an extracellular structure referred to as needle,^{2,3,6–8} pilus⁹ or filament,^{10–12} depending on the family of injectisomes. Upon contact with the eukaryotic host cell, a set of effector proteins that subvert host cellular functions to the pathogen's benefit is translocated into the eukaryotic cytoplasm.^{13,14}

The rotationally symmetric basal body of the T3S system (T3SS) actively exports the components of the extracellular needle structure.^{3,4,15,16} The length of the *Yersinia* injectisome needle, assembled from the 9 kDa protein YscF, differs from species to species. In *Yersinia enterocolitica*, the needle length of ~60 nm correlates with the length of the “molecular ruler” protein YscP.¹⁷ A needle tip complex, made of the

Abbreviations used: YscU^C, C-terminal domain of YscU comprising amino acids 211–354; T3SS, type III secretion system.

protein LcrV,¹⁸ functions as a scaffold to assemble a pore in the target cell membrane consisting of YopB and YopD, through which T3SS effectors are translocated into the host cell.¹⁹ Beside the “molecular ruler” model,¹⁴ two other models for needle/hook length control, the cup model²⁰ and the molecular stopwatch mechanism,²¹ are discussed. As a clear hierarchy in the synthesis of the needle components is not discernible, the T3SS presumably discriminates between substrate classes to assemble this complex molecular machine.²² Needle assembly depends on the export of early substrates such as the needle subunit YscF and the molecular ruler YscP. Thereafter, the system switches its substrate specificity to intermediate (translocators) and late (effectors) export substrates. The substrate specificity switch is thought to involve at least two proteins, the molecular ruler YscP and the inner membrane protein YscU.^{23,24}

In the 40 kDa membrane protein YscU, four N-terminal transmembrane helices are followed by a globular cytoplasmic domain (YscU^C).²⁵ The latter, which was originally found in the C-terminal cytoplasmic domain of the *Salmonella* flagellar YscU homolog, FlhB,²⁶ is cleaved autoproteolytically within a conserved NP_{TH} sequence.²⁷ Autocleavage, however, is abrogated by substituting either asparagine or proline by alanine.²⁷ Bacterial mutants carrying these substitutions no longer export translocator proteins (YopB, YopD and LcrV), whereas export of effector proteins is not affected.²² Cleaved YscU thus appears to discriminate between translocator and effector proteins. The mutant *yscU*_{N263A}, furthermore, secretes less YscP and makes longer needles.²²

Here, we report the crystal structures of the non-cleavable YscU^C_{N263A} and YscU^C_{N263D} variants from *Yersinia enterocolitica* and compare them to the related structures of EscU, SpaS²⁸ and Spa40.²⁹ Based on the structural information, additional YscU^C mutants were designed to elucidate their *in vitro* autocleavage behaviour and the nature of the resulting *in vivo* phenotypes.

Results

Crystal structures of YscU^C N263A and N263D

The YscU^C variants N263A and N263D readily yielded well-diffracting tetragonal crystals. Crystallization of cleaved, wild type YscU^C, by contrast, was not successful. The structure of YscU^C N263A was solved using SeMet-based multiwavelength anomalous diffraction (MAD) phasing. Two (of four expected) selenium positions were sufficient to build an initial model, which was refined at a resolution of 2.05 Å (Table 1). The isomorphous structure of YscU^C N263D was refined at a resolution of 1.55 Å (Table 1).

The globular domain of uncleaved YscU^C (Fig. 1) consists of a central, five-stranded, mixed β -sheet (I–

V), surrounded by four α -helices (1–4). α -Helix 3 is almost perpendicular to the strand orientation of the central β -sheet. The NP_{TH} cleavage motif forms a type II β -turn connecting β -strands I and II, with position 263 located at the C-terminal end of β -strand I.

The globular autocleavage domain is preceded by an extended N-terminal loop containing a well defined α -helix (α 0) comprising residues 231–246. This helix forms an antiparallel interaction with helix 4 of a symmetry-related YscU^C monomer in the crystal.

Structural basis for autocleavage of YscU

Close inspection of the modified NP_{TH} motif in the isosteric variant YscU^C N263D (DPTH, Fig. 2a) shows that the main-chain carbonyl of Asp263 is tightly locked into position *via* hydrogen bonds to the backbone nitrogen atoms of His266 and Ile267. This structural stiffness is enhanced by the peptide bond of Pro264. All main-chain dihedral angles of the DPTH residues fall in the allowed regions of the Ramachandran plot, indicating no obvious conformational strain. A salt bridge with the guanidinium group of Arg314 positions the side chain of Asp263 above its main chain carbonyl group.

The ideal entry angle for a nucleophilic attack of a carbonyl group has been proposed to lie between 100° and 110°, and a distance between nucleophile and electrophile of <2.5 Å.^{30,31} The corresponding angle of the YscU^C N263D variant is 109° with an N–C distance of 2.8 Å. The β -amide nitrogen of Asn263 would therefore be positioned perfectly for a nucleophilic attack. Furthermore this geometric arrangement favours a stabilizing orbital overlap (Fig. 2b), where the anti-bonding σ^* -molecular orbital (MO) of the $C\alpha_{Asn}-N_{Asn}$ bond interferes with the nascent bonding σ -MO of the C(=O)–N bond in native YscU.

Cleavage does not affect the overall structure of wild type YscU^C

Recombinantly produced wild-type YscU^C is readily cleaved into a ~6.3 kDa N-terminal (α -helices 0–1 and β -strand I) and a ~10.5 kDa C-terminal (α -helices 2–4 and β -strands II–V) fragment. The fragments remain tightly linked, however,²⁷ resulting in a single peak in gel-filtration chromatography (data not shown). Cleavage of the wild-type protein thus does not cause significant overall structural rearrangements compared to the uncleaved YscU^C variants. This was confirmed by 2D NMR (¹⁵N, ¹H HMQC) spectroscopy by comparing ¹⁵N-labelled wild type and N263A YscU^C (Fig. 3). Overall, wild type YscU^C shows a good dispersion of the signals, characteristic for a folded globular conformation. An equally good dispersion of the signals is observed for N263A YscU^C. The NMR spectra of wild type and N263A YscU^C superimpose very well, with most peak positions being virtually identical and line-widths apparently unaffected. Cleaved and un-

cleaved YscU thus share the same overall structure with minor, but physiologically highly relevant, changes in and close to the NPTH motif.

The role of conserved amino acids in YscU^C cleavage *in vitro*

Substituting the nucleophile Asn263 by alanine, aspartate and glutamine abolishes autocleavage of YscU. While Asn263 is thus essential for YscU autocleavage, the role of surrounding residues is less clear. A systematic mutational analysis of the NPTH motif reveals an active participation of Pro264 and His266 in YscU autocleavage (Fig. 4a and b), whereas Thr265 is not involved.²² Substitution of Pro264 by alanine reduces cleavage of YscU^C significantly, whereas substitution by glycine prevents cleavage altogether. Variant H266A shows a partial cleavage of YscU^C. The structure of YscU^C shows that two arginine residues (Arg296 and 314) flank the NPTH motif. Of these, Arg314 is highly conserved, Arg296 less so. Substituting Arg314 by alanine correspondingly reduces cleavage partly, whereas cleavage of variant R296A is unaffected. Interestingly, cleavage is entirely abrogated in the

double variant H266A/R314A, suggesting a synergistic involvement of these residues in the mechanism of cleavage.

Cleavage of some autocleavage-deficient YscU mutants is partially restored at high pH

Autocleavage of the slow-cleaving variant P270A of the flagellar protein FlhB^C (a homologue of YscU^C) has been reported to be pH-dependent.³² YscU^C variants N263D, P264G, P264A and H266A/R314A were therefore analysed at pH 9, 10 and 11 (Fig. 4c). In variant N263D, no cleavage was observed at higher pH values, whereas P264G, P264A and H266A/R314A were partially cleaved only at elevated pH. These observations match the published data on FlhB P270A,³² suggesting that the nucleophile Asn263 needs to be activated by deprotonation of its side chain amide group.

YscU mutants that are not cleaved *in vitro* do not export the translocator LcrV

Next, the export of the LcrV protein in the corresponding *Yersinia* mutant strains was investigated.

Fig. 1. Ribbon plot of the monomer of YscU^C N263A. The position of the mutation in the cleavage site is indicated by an asterisk (*). After cleavage YscU^C is divided into an N-terminal and a C-terminal half, shown in brown and green, respectively. The modified NPTH motif, as well as Arg314 and Arg296, are depicted as stick-and-ball models.

Secretion was not affected for wild type YscU, and the variants H266A, R314A and R296A, but is lost in variants N263A, N263D, N263Q, P264A, P264G, and H266A/R314A, as confirmed by an immunoblot of the supernatant (Fig. 5). The LcrV secretion pattern is in excellent agreement with the data described above for *in vitro* autocleavage.

The T3SS injectisome needle length is influenced strongly by YscU mutations

The influence of the YscU modifications on needle length was investigated by measuring needles from *Y. enterocolitica* $\Delta yscU$ mutant bacteria expressing the respective mutants *in trans*. Bacteria expressing wild type *yscU* produced regulated needles of 69 ± 10 nm. Similar needle lengths were measured for the YscU variants H266A (67 ± 9 nm), R314A (72 ± 12 nm), and R296A (76 ± 11 nm). In contrast, the length of needles in YscU variants N263A (125 ± 40 nm), N263D (143 ± 51 nm), P264A (112 ± 42 nm), and P264G (114 ± 30 nm) was longer and less regulated. Interestingly, YscU variants N263Q (80 ± 16 nm) and H266A/R314A (77 ± 15 nm) were regulated with a length distribution slightly larger than that of wild type YscU (Fig. 6).

Discussion

YscU is poised for autocatalytic cleavage

To elucidate the structural basis of YscU^C autocleavage, the crystal structures of YscU^C variants N263A and N263D were determined at high resolution. Additional single-residue YscU^C variants within the NPTH motif or its immediate vicinity were investigated with respect to their participation in cleavage and needle-length control.

The crystal structure of non-cleaving YscU^C variant N263D (the asparagine nucleophile is replaced by the isosteric homologue aspartate) suggests that the side chain of Asn263 is positioned ideally for a nucleophilic attack and subsequent cleavage of wild-type YscU^C. In N263D, the attack on its own carbonyl is prevented by the insufficient nucleophilicity of the Asp263 carboxylate, despite its equivalent positioning. In N263Q, the nucleophilicity should be similar to that of asparagine. However, the longer, and hence more flexible, side chain disfavours the formation of a lactam ring in this variant, preventing cleavage of YscU^C.

YscU^C autocleavage is crucially dependent on the positioning of the attacked carbonyl group of

Fig. 2. (a) Detailed stereoview of the modified NPTH motif of YscU^C N263D. The C-terminal and N-terminal halves are shown in brown and green, respectively. The isosteric Asp263 is positioned optimally (109°) for a nucleophilic attack, as indicated by the broken red line. Hydrogen bonds are indicated by broken black lines. The $(2F_O - F_{C,\alpha C})$ electron density map of the cleavage site is depicted at a contour level of 1.5 σ . (b) Orbital model illustrating the stabilizing orbital overlap. The anti-bonding σ^* -molecular orbital (MO) of the C α -N bond in Asn263 (blue) interferes with the nascent bonding σ -MO of the C(=O)-N-bond (red).

Asn263, which is part of the peptide bond to Pro264. Increased flexibility of the main chain correspondingly disfavours cleavage in the variants P264A and P264G. As indicated above, cleavage is less efficient in variants H266A and R314A, but abrogated entirely in H266A/R314A. Raising the pH increases cleavage, implicating both His266 and Arg314 in efficient autocleavage. By means of a hydrogen bond, Arg314 presumably serves to optimally position the side chain of Asn263 allowing nucleophilic attack to occur at an angle of 109°. The role of His266 is, however, less clear. It may potentially mediate the abstraction of a proton from

Asn263 either directly or by deprotonating an intermediate water molecule. A similar phenomenon has been proposed for a histidine residue during autosplicing of the DnaB mini-intein.³³ Thr265, the only imperfectly conserved amino acid of the NPTH motif, does not appear to be involved directly in the cleavage reaction.^{22,28} A preference for β -branched amino acids indicates a role in stabilizing the type II turn.³⁴

Our results are supported by similar structural and functional data reported recently for the YscU homologues EscU from enteropathogenic *E. coli*, SpaS from *Salmonella typhimurium*²⁸ and Spa40 from

Fig. 3. The $^{15}\text{N}, ^1\text{H}$ HMQC NMR spectra of YscU^C. The contour lines of wild type YscU^C are orange, and those of YscU^C N263A are black.

Shigella flexneri.²⁹ The crystal structures of the cleaved wild type EscU as well as a number of EscU variants were determined and correlated with *in vivo* cleavage experiments of full-length EscU (variants). Wild type EscU, SpaS and Spa40 reveal unchanged tertiary structures of nicked proteins, concurring with our conclusion based on NMR-analysis of YscU^C wild type and mutant.

The only major differences concern YscU^C variants H266A and R314A and their homologous variants *in vivo* in full-length EscU. Both YscU^C variants show partial autocleavage *in vitro* and a wild type-like secretion of LcrV *in vivo*. EscU variant H265A is found to be fully autocleaved but secretion of T3S substrates is lost.²⁸ EscU variant R313A, by contrast, remains uncleaved but again T3S substrates secretion is lost.²⁸ A third EscU variant, R133T, is fully cleaved but retains normal effector secretion.²⁸ Thus, despite a high level of structural conservation between YscU and EscU, some differences between the *Yersinia* and EPEC T3SS may exist. The *in vitro* cleavage data on YscU^C His266 variants would presumably implicate His265 in EscU in the asparagine-driven autocleavage reaction.

We propose the following autocleavage reaction mechanism (Fig. 7). (i) The unique reaction geometry of YscU and its homologues is a prerequisite for the nucleophilic attack. The β -amide nitrogen, activated through proton abstraction by His266 or an intermediate water molecule, is optimally positioned to attack the electrophilic carbonyl carbon at an angle of 109° (108° in EscU). (ii) The tetrahedral reaction intermediate is stabilized by hydrogen bonds to the backbone amides of His266 and Ile267. (iii) Protein

cleavage gives rise to a labile succinimide, which is rapidly hydrolysed to yield a new C-terminal asparagine or iso-asparagine.

The structure of YscU^C also explains phenotypes of previously reported YscU variants. The strongly reduced export of the presumed inner rod protein YscI (in an *yscPyscU* mutant background) in the YscU variant Y317D implicates Tyr317 in interacting directly with YscI.³⁵ Structurally, this strictly conserved residue is fully exposed at the surface of α -helix 3. Presumably, the introduction of a negative charge prevents interaction with YscI explaining the observed phenotype.²⁸ The YscU variant G270N has been reported to cause the complete loss of T3S and YscU autocleavage.³⁶ Gly270, in the middle in β -strand II, is fully buried in the hydrophobic core of the domain. Replacing this by the significantly bulkier asparagine presumably prevents correct protein folding, resulting in the loss of this protein and non-functional T3SS.

Needle length in a non-cleavable YscU mutant is controlled even without YscP over-expression

In vivo analyses reveal a new phenotype for the YscU variants N263Q and H266A/R314A. These variants do not undergo autocleavage *in vitro*. Corresponding bacterial mutants do not secrete the translocator LcrV. Their needles are, however, of normal size, although significantly less YscP is secreted compared to wild type bacteria (data not shown). In the YscU N263A mutant, wild type needle length could be restored only by YscP over-expression implying that YscU autocleavage inhibition diminishes YscP

Fig. 4. Cleavage behaviour of different YscU^C variants expressed in *E. coli*. (a) Coomassie brilliant blue-stained SDS/15% PAGE analysis of cells producing various YscU^C variants. (b) Over-expressed cells analysed by immunoblotting using an anti-YscU^C antibody. (c) The pH-dependent cleavage of YscU^C-variants. SDS-PAGE analysis of purified YscU^C-variants incubated at different pH values.

secretion losing control over needle length.²² The phenotype observed here for the variants N263Q and H266A/R314A demonstrates that the inhibition of the autocleavage may indeed affect the secretion of YscP and LcrV without relinquishing control over needle length. The fact that different phenotypes are observed for N263A and N263Q despite involving the same residue, may indicate that small amounts of YscP are sufficient to determine needle length but that a defined conformation of YscU is also required.

The flexible linker region is composed of two hinged α -helices

A structural superposition of uncleaved YscU^C variant N263A with EscU^C (rmsd 1.3 Å for 94 common C α atoms), SpaS from *Salmonella typhimurium* (rmsd 1.0 Å for 80 C α atoms), and Spa40 from *Shigella flexneri* (rmsd 1.0 Å for 82 C α atoms) reveal virtually identical folds for the cytoplasmic core region and

Fig. 5. Analysis of LcrV secretion by different yscU mutants. Total cell (TC) and supernatant (SN) fractions of corresponding *in trans* complemented *Yersinia* $\Delta yscU$ mutant bacteria analysed by immunoblot with anti-LcrV antibodies.

the NPTH motifs (Fig. 8b), despite a low level of overall sequence identity (Fig. 8a).

An obvious difference between YscU^C and its homologues EscU^C, SpaS^C and Spa40^C involves the proposed flexible linker (211–248) connecting the globular autocleavage domain to the N-terminal membrane-spanning four-helix bundle (Fig. 8b). In YscU^C, amino acids 232–244 form a well-defined α -helix, which is not observed in the homologous

structures. In the crystal structure of YscU^C, α -helix $\alpha 0$ is involved in a crystal contact to α -helix $\alpha 4$ of the next monomer. One of the crystal forms of EscU^C reveals a further α -helix (α -1) N-terminal of $\alpha 0$.²⁸ The presence of α -helix $\alpha 0$ confirms earlier predictions of the secondary structure for the flagellar protein FlhB.³⁷

The linker region is essential for T3S.²⁸ Corresponding deletions 232–236, 234–245 and 230–245 in

Fig. 7. Structure-based model of succinimide-mediated cleavage of YscU. (I) His266 (or a His266-activated water molecule) abstracts a proton from the β-amide nitrogen of Asn263. The latter makes a nucleophilic attack on the Asn263 carbonyl, resulting in the rate-limiting tetrahedral intermediate (II). Cleavage of the peptide bond yields a labile C-terminal succinimide (III), which is hydrolysed to asparagine or iso-asparagine.

EscU and the point mutation G235P (S236P in YscU) abolish the export of T3S substrates, despite auto-cleavage of EscU being detectable. Similar results have been obtained for the FlhB protein.³⁷ Mapping these mutations onto the structure of YscU^C indicates that each would delete or kink α-helix α0, which presumably functions as a spacer element, separating the globular autocleavage domain from the inner membrane. Additionally, the helix could be involved in direct or indirect binding of other components.

Amino acids such as Gly229 and Gly248 in EscU are assumed to provide flexibility to the linker region.²⁸ Substituting conserved Gly229 by proline in EscU (G230 in YscU and located N-terminal of α-helix α0) decrease the export of T3S substrates dramatically. An equivalent substitution in Gly247 (G248P in YscU and located C-terminal of α0) also reduces the export of T3S substrates. Combining the structural information on YscU^C and EscU^C with the *in vivo* data suggests that YscU-like proteins are composed of three units (Fig. 9): A membrane-spanning N-terminal domain and a C-terminal, cytoplasmic, globular, autocleavage domain bridged by a flexible linker region that can switch from an extended to a partially α-helical conformation. This adaptable architecture of the linker allows for

sufficient conformational freedom to enable interactions of the autocleavage domain with other components of the T3SS during T3SS assembly.

Materials and Methods

YscU *in vivo* experiments

Bacterial strains, plasmids and genetic constructions are given in [Supplementary Data Table 1](#). *E. coli* Top10 was used for plasmid purification and cloning. Bacteria were grown routinely on Luria-Bertani (LB) agar plates and in liquid LB medium. Ampicillin was used at concentrations of 200 µg/ml.

Plasmids were generated using either the *Pfu* turbo polymerase (Stratagene) or Vent DNA polymerase (New England, Biolabs). Oligonucleotides for genetic constructs are given in [Supplementary Data Table 2](#). All constructs were confirmed by sequencing using a 3100-Avant genetic analyser (ABI Prism).

LcrV secretion and immunoblotting

Induction of the *yop* regulon was as described by Cornelis et al.³⁸ Expression of the different genes cloned downstream of the pBAD promoter was induced routinely by adding 0.2% l-arabinose to the culture before the shift to

Fig. 8. (a) Structure-based sequence alignment of YscU^C from *Y. enterocolitica* (Swiss-Prot. accession number Q56844) with FlhB^C from *S. typhimurium* (P40727), EscU^C from *E. coli* (Q7DB59), SpaS^C from *S. typhimurium* (P40702), Spa40^C from *S. flexneri* (Q6XVW1) and HcrU^C from *X. oryzae* (Q5H6T1). The secondary structures are from YscU^C N263D. Conserved amino acids are marked in bold letters on coloured backgrounds. Substituted residues in this study are indicated by a yellow background. Less well conserved amino acids are in bold and coloured blue. (b) A stereoview of the YscU^C variant N263D (green) superimposed on its wild type homologues EscU^C (blue), SpaSC (grey) and Spa40^C (orange). Important positions are marked by a green sphere.

37 °C, and again 2 h later. Glycerol (4 mg/ml) was added as a carbon source when expressing genes from the pBAD promoter. Total cell and supernatant fractions were separated by centrifugation at 20,800g for 10 min at 4 °C. The cell pellet was taken as the total cell fraction. Proteins in the supernatant were precipitated with 10% (w/v) trichloroacetic acid (final concentration) for 1 h at 4 °C.

Supernatant (SN) and total cell (TC) fractions were separated by SDS/12% PAGE. In each case, proteins secreted (SN) or produced (TC) by 2.5×10^7 bacteria were loaded in each lane. Immunoblotting was done using rabbit polyclonal antibodies against LcrV (MIPA220; 1:2000). Detection was done with the respective secondary antibodies conjugated to horseradish peroxidase (1:5000; Dako), before development with supersignal chemiluminescent substrate (Pierce).

Electron microscopy

Needles were visualized by transmission electron microscopy as described.^{8,23} After induction of the *yop* regulon at 37 °C for 4 h bacteria were harvested by centrifugation at 2000g and suspended gently in 20 mM Tris-HCl, pH 7.5. Droplets were applied for 1 min to

freshly glow-discharged, formvar-carbon coated grids, and negatively stained with 2% (w/v) uranyl acetate. Bacteria were visualized in a Philips CM100 transmission electron microscope at a nominal magnification of 20,000 \times and an acceleration voltage of 80 kV. Sizes were measured with Soft imaging system software (Hamburg, Germany).

Expression and purification of YscU^C

The cytoplasmic domain of YscU^C was expressed in *E. coli* Tuner (DE3) cells using vector pGEX-6P-1 (GE Healthcare). A single colony was used to inoculate a preculture of 20 mL of L-B medium with 100 μ g/mL of ampicillin. The cells were grown at 37 °C to an A_{600} of 0.6. A 10 mL preculture was transferred in 1 L of Terrific Broth (100 μ g/mL of ampicillin), grown at 37 °C to an A_{600} of 0.6, supplemented with 0.2 mM isopropyl thiogalactopyranoside, incubated for 16 h, and then harvested by centrifugation.

Harvested cells were resuspended in PBS, containing 2 μ L of Benzonase (250 U/mL, Novagen) and one tablet of Complete Mini Protease Inhibitor (Roche). Cells were lysed by French press and centrifuged. The supernatant was incubated with glutathione Sepharose (GS, GE Healthcare)

Fig. 9. Model of the tripartite domain arrangement of YscU. The N-terminal, membrane-spanning domain is followed by a flexible linker region and a globular autocleavage domain.

for 4 h at 4 °C. Unbound protein was washed three times from the GS column with protease buffer (50 mM Trizma base, pH 7.5, 150 mM NaCl, 1 mM DTT, 1 mM EDTA). A 75 µL sample of PreScission Protease (GE Healthcare) in 10 mL of protease buffer was incubated with loaded GS overnight at 4 °C. The protein was eluted four times with protease buffer and dialysed against buffer A (20 mM Hepes, pH 7.0, 100 mM NaCl). The protein solution was applied to a cation-exchange column (MonoS, GE Healthcare) equilibrated with buffer A and eluted with a 0.1 M – 1 M NaCl gradient in buffer A. The YscU^C-containing fractions were identified by SDS-PAGE, concentrated to 5–15 mg/mL and further purified using a gel permeation column (Superdex S75 16/60, GE Healthcare) equilibrated with 20 mM Hepes, pH 7.0, 150 mM NaCl. I-Selenomethionine (SeMet)-labelled and ¹⁵N-labelled YscU^C N263A, as well as ¹⁵N-labelled YscU^C wild type were produced as described.³⁹ YscU^C mutations were introduced using the QuikChange kit (Stratagene) and verified by DNA sequencing (GATC, Konstanz, Germany). YscU^C variants were purified as described above.

Preparation of pH-dependent cleavage

The different YscU^C variants were expressed and purified as described above. P264A was dialysed against 25 mM Ches buffer (pH 7.0, 9.0 and 10.0), 100 mM NaCl for 3 h at room temperature. P624G, H266A/R314A and N263D were dialysed against 25 mM Caps (pH 7.0, 10.0

and 11.0) buffer, 100 mM NaCl for 4 h at room temperature. Afterwards, the solution of protein P264G was stored for 48 h and H266A/R314A and N263D were stored for 24 h at 4 °C. Cleaved proteins were submitted to SDS/15% PAGE and stained with Coomassie brilliant blue.

Crystallization and structure determination

YscU^C N263A and its SeMet-labelled derivative were crystallised using the hanging drop method using 3 µL of a 8 mg/mL protein solution mixed with 3 µL of reservoir buffer (1.6 M (NH₄)₂SO₄, 0.2 M NaCl, 0.1 M Hepes, pH 7.5) in the droplet. Crystals grew within ~4 days at 20 °C to sizes of up to 180 µm × 180 µm × 120 µm. Crystals were transferred in cryo buffer containing reservoir buffer with 16% (v/v) glycerol as a cryoprotectant and flash-frozen at 100 K in liquid nitrogen. Four multiwavelength anomalous diffraction (MAD) data sets of SeMet-labelled YscU^C N263A were collected at beamline X12 at the EMBL Outstation (Hamburg, Germany), and processed with the HKL2000⁴⁰ and MOSFLM.⁴¹ Localization of two selenium sites, which were used for phasing and the generation of a partial model, was done with AUTORICKSHAW.⁴² Manual model building was carried out using COOT⁴³ and refinement was completed using REFMAC5.⁴⁴

The X-ray data set of YscU^C N263D was collected at ESRF beamline ID29 (Grenoble, France), processed with MOSFLM⁴¹ and scaled with SCALA.⁴⁵ Using REFMAC5⁴⁶ and SeMet-labelled YscU^C N263A as a phasing model, the

structure was solved by difference Fourier and further refined with COOT⁴³ and REFMAC5.⁴⁴

The validation of both structures was done with MOLPROBITY.⁴⁷ Data collection and refinement statistics are given in Table 1. Figures were prepared using PyMOL†.

NMR analysis

For NMR spectroscopy, we used a 12 mg/mL solution of uniformly ¹⁵N-labelled YscU^C in a mixed solvent of 95% (v/v) H₂O, 5% (v/v) ²H₂O and a 10 mg/mL solution of YscU^C N263A in the same solvent. The NMR samples contained 50 mM NaCl, 3 mM KCl, 12 mM Na₂HPO₄ and 2 mM KH₂PO₄ at pH 6.8. The Bruker Advance III 600 spectrometer used for this study was equipped with a 5 mm Z-axis gradient triple-resonance cryo-probehead. The 2D [¹⁵N, ¹H] correlation spectra were recorded at ω₁ = 2100 Hz and ω₂ = 8400 Hz. The maximal evolution times were t_{1max} = 60 ms and t_{2max} = 240 ms and the time domain data size was 256 × 2048. Programs PROSA⁴⁸ and CARA⁴⁹ were used for data processing and spectral analysis, respectively.

Protein Data bank accession codes

The coordinates have been deposited in the Protein Data bank (PDB) under accession code 2v5g and 2w0r.

Acknowledgements

We thank Hauke Pagel for his support during the initial stage of protein preparation. We are grateful to Dr Manfred Weiss (DESY/ EMBL, beamline X12), the team of ESRF-ID29, for helping during data collection and processing. We are grateful to Dr Victor Wray and Dr Wolf-Dieter Schubert for critical comments on the manuscript. D.W.H. acknowledges support by the Fonds der Chemischen Industrie. This work was supported by the Swiss National Science Foundation (grant 310000 – 113333/1 to GRC).

Discussion

Length control of the injectisome needle is a crucial step in the assembly of a functional secretion machinery. Different models have been postulated to explain the control mechanism. However, the exact mechanism still remains unclear and the aim of this thesis was to refine the model of length control of the type III secretion injectisome needle.

The protein YscP of *Y. enterocolitica* has two repeated segments [125] within the second ruler region and a high proline content. Sequence comparison of different YscP proteins revealed that the percentage of proline residues and the content of predicted α -helices varies [157]. By proline substitutions and molecular dynamics calculations it could be shown, that not only the number of residues of YscP but also its helical content correlates with needle length [157]. These new data support the molecular ruler model as published by Journet *et al.* [53] which was evocative of the molecular ruler proteins controlling the length of bacteriophage tails [66, 67, 73]. Confirming a direct correlation between the length of the ruler protein and the length of the injectisome needle contradicts the 'inner rod model' which was proposed for length regulation in *Salmonella* [123]. Here, InvJ, the YscP homolog, is proposed to stabilize the socket structure and not to act as a molecular ruler, tape measure, or molecular timer. In this model a direct correlation between needle and InvJ length would not be necessary.

The ruler model in its original form suggests that one molecule of YscP determines the length of one injectisome needle. This implies that YscP and the needle subunit YscF travel inside the growing needle at the same time. Modeling a partially helical YscP protein showed only a partial occupation of the needle channel [157] and thus renders the above assumption possible. However, more than one molecule of YscP could be involved in needle length control. In a dynamic ruler model, YscP and YscF would be exported alternately. In this model YscP could only switch substrate specificity, when the needle has the right length for YscP to be in the right position to switch. In order to distinguish between the two possible models, the number of YscP molecules needed for needle length determination was investigated (Wagner *et al.*, submitted). By a genetic approach, two different variants of YscP - a long and a short one - were expressed in one bacterium. These bacteria

exported both variants and analyzing needle length revealed two distinct needle populations (one population of short needles and a second population of long needles). The experimentally obtained needle length distribution was analyzed mathematically and compared to the distributions predicted by mathematical modeling of the various possible scenarios. The experimental data are compatible with the single ruler model and not with the scenarios involving more than one ruler per needle. These data suggest that one needle is controlled by only one molecule of YscP, as proposed by the ruler model in its original form (Wagner *et al.*, submitted; [53]). This fact is moreover supported by the observations published, by Agrain *et al.* [126] and Wiesand *et al.* [158], that very small amounts of YscP are sufficient to control needle length. In addition, a correlation between the number of needles of a given length and the amount of secreted YscP of that length was observed. This emphasizes the observation that YscP needs to be secreted to fulfill its function. These data contradict the interpretation by Shibata *et al.* [113], who proposes that FliK acts as an internal ruler without being secreted. As mentioned before, the data published by Aizawa and coworkers [113] are, however, not conclusive.

Another question was to understand whether YscP determines the needle length by acting as a molecular ruler or rather as a timer. In the first case, the sequence length of YscP determines needle length, whereas in the second case the time of YscP secretion would determine needle length. For *Shigella* and *Salmonella*, over-expression of the needle subunit (MxiH or PrgI, respectively) leads to elongated needles [31, 123]. These results favour the timer model, when over-expression results in an enhanced/faster export of the needle subunit. In *Y. enterocolitica* elongated needles were only observed upon over-expression of the entire operon *yscEFGHI* (Isabel Sorg, unpublished data, see pages 136-137). To test the timer model, the effect of decreased expression of YscEFGHI was subsequently tested. Decreased expression of YscEFGHI led to very low amounts of needles which were of wild type length (pages 136-137). These results do not support a molecular timer model. The elongated needle length observed while over-expressing YscEFGHI might result from a delayed switching process, due to an increased export rate of the small Ysc proteins.

Assuming the ruler model as proposed by Journet *et al.* [53] is correct, YscP must interact with other proteins in order to fulfill its function. These proteins are most likely located at the base of the basal body and at the tip of the growing needle. Since a ΔLcrV mutant strain assembles wild type needles [157] the tip forming protein LcrV can be excluded as binding partner. Several small Ysc proteins (YscI, YscH, YscX and YscO) are secreted as early substrates but the function of these proteins is unknown. Another possible mechanism: YscP forms an umbrella-like structure at the tip of the growing needle which serves as a cap or anchor to sense the distal needle end. For this, an additional binding partner (besides YscF) at the distal needle end would not be necessary. Polymerization of the needle could be the driving force for export of YscP in this model of needle length control. A binding partner at the base of the basal body, however, remains a prerequisite to switch substrate specificity. In the flagellum, FliK was inferred to interact with the soluble carboxy-terminal domain of FlhB (FlhBc) [116]. This interaction plays a crucial role in the switch from hook to filament secretion in the flagellum system. Botteaux *et al.* [132] showed by immunoprecipitation experiments that Spa32, the *Shigella flexneri* homolog of YscP, interacts with Spa40 the homolog of YscU. These data together with the results by Sorg *et al.* [130] show a role for YscU in substrate recognition, suggest an interaction between YscP and YscU in *Y. enterocolitica*. In this thesis, two different experiments to test for interactions between YscU and YscP were done which could later be useful for identification of other binding partners of YscP. The YscP Δtail (YscP $\Delta\text{500-515}$) mutant was included in this study as a control which is not exported by the type III secretion machinery (pages 138-141). The YscP tail might be important for correct recognition of YscP or for correct interaction with its binding partner(s) to switch substrate specificity as suggested for FliK [109]. Preliminary results could not confirm a binding between YscP and YscU, but further investigation is necessary.

The injectisome exports its own distal components before it exports the effectors, which implies that the type III secretion apparatus can recognize and sequentially export different categories of substrates. For this purpose, the apparatus is believed to switch its substrate specificity after completed assembly. Encouraged

by the results for the flagellum where FliK and FlhB are both involved in the substrate specificity switch [105, 116], the role of YscU was investigated in more detail.

For a detailed understanding of this sequential export process, mutations were introduced in the NPTH cleavage site of YscU. In contrast to previous reports on FlhB [116] and YscU [129], the phenotypes resulting from over-expression of cloned *yscU* alleles, and from replacement of the *yscU* alleles on the pYV plasmid to ensure physiological expression levels were analyzed. The results confirmed a cleavage of the 40-kDa YscU into a 30-kDa TM + CN fragment and a 10-kDa CC fragment, as shown previously for FlhB [116] and for YscU from *Y. pseudotuberculosis* [129]. A CC fragment was not detected for the mutant proteins YscU_{N269A} and YscU_{P264A}, confirming the results by Lavander *et al.* [159] using C-terminal tagged YscU. The *yscU*_{N263A} mutant bacteria assembled injectosome needles, but their length was poorly controlled and the median length was almost double the size (111 nm) than for wild type bacteria (67 nm). When the *yscU*_{N263A} allele was combined with a longer (680 codons) and a shorter (388 codons) allele of *yscP*, the median needle lengths were 222 nm and 91 nm, respectively, indicating that needle length was still dependent on the length of the YscP ruler, although the standard deviation was much larger. In addition to this loose length control, the *yscU*_{N263A} bacteria released less YscP into the culture supernatant than wild type bacteria. The intrabacterial amount of the protein, however, was unchanged. To overcome the poor export efficiency of YscP, the gene was over-expressed downstream from the pBAD promoter. As expected from previous work by Agrain *et al.* [126], over-expression of the three different *yscP* alleles led to a higher export of YscP proteins and to a better control of needle length. The latter was as good as in *yscU*_{wt} bacteria. Hence, it can be concluded that the *yscU*_{N263A} mutation reduces the efficacy of the type III secretion system to export or recognize YscP, which indirectly leads to a less stringent control of needle length. Furthermore, the *yscU*_{N263A} mutation does not affect the capacity of the type III secretion export apparatus to switch off the export of the YscF needle subunits when the needle reaches its genetically defined length. Thus, cleavage at the NPTH motif is not required to switch off needle subunit export. The same variants of YscU and YscP can give rise to two different needle lengths,

depending on the amount of YscP exported. This excludes YscU playing a role as a timer to determine needle length, as proposed for the flagellar hook length control [118].

yscU_{N263A} mutant bacteria were able to release effector Yops, to a slightly lower extent than wt bacteria. Hence, the *yscU_{N263A}* mutation does not affect the substrate specificity switching from early (YscF, YscP) to late (Yops) substrates. The most intriguing phenotype of the *yscU_{N263A}* mutation was the deficiency in export of the translocators LcrV, YopB and YopD. Our results [130] confirmed that YscU plays a critical role in substrate recognition, particularly the structure of the CC fragment. Furthermore, the translocators are specifically recognized by YscU. Thus, the injectisome has at least three classes of substrates. However, evidence for a specific role of the cleavage of the CC fragment in the substrate specificity switch was not found.

The crystal structures of the cytoplasmic domain of YscU (YscU_c) variants N263A and N263D were determined at high resolution [158]. Additional single-residue YscU_c variants in the NPTH motif or its immediate vicinity were investigated with respect to their participation in cleavage and needle-length control. The observed phenotype of variants N263Q and H266A/R314A demonstrates that inhibition of auto-cleavage of *yscU* affects secretion of YscP and LcrV without relinquishing control over needle length. Different phenotypes are observed for N263A and N263Q, indicating that small amounts of YscP are sufficient to determine needle length when YscU is in the correct conformation. This is supporting the ‘one ruler per needle’ model as described above. Preliminary experiments of *yscU_{N263Q}* under physiological conditions (under its native promoter) showed the needle of the new mutant to be shorter than needles from the cleavage site mutant (81 ± 26 nm *versus* 111 ± 43 nm; [130]) but length regulation was not as tight as in wild type bacteria (67 ± 10 nm; pages 134-135). Combining the structural information on YscU_c and EscU_c [158, 160] with the *in vivo* data suggests that YscU-like proteins are composed of three units: a membrane-spanning N-terminal domain and a C-terminal, cytoplasmic, globular, auto-cleavage domain bridged by a flexible linker region that can switch from an extended to a partially α -helical conformation. This

adaptable architecture of the linker gives sufficient conformational freedom to enable interactions of the auto-cleavage domain with other components of the type III secretion system during its assembly.

Based on these results a refined model for length control of the injectisome needle in *Yersinia* can be proposed. The data presented in this thesis suggest that YscP acts as a molecular ruler. One molecule of YscP would measure the length of the growing needle. Whether YscP is anchored at both ends and stretches or whether it is exported during this process (co-translationally or with the help of a chaperone) still remains unclear. Hints for the latter possibility are the direct correlation between the partially folded YscP and the injectisome length. Moreover, the observation that YscP is insoluble and the predicted secondary structure suggest either co-translational export or a need for a chaperone. Since no polymerization cap has been identified and the ΔcrV strain assembles needles of wild type length [157], the N-terminal part of YscP is believed to be outside the needle channel with a certain structure replacing the cap. During needle growth YscP is pulled out of the bacterium. Once the C-terminal domain of YscP (T3S4 domain) is in the right position to interact with its binding partner at the basal body, substrate specificity switches and consequently terminates needle growth. Whether this binding partner is YscU or another member of the export machinery needs further investigation. Furthermore, it remains unclear whether YscP and the needle subunit YscF are exported *via* the same channel in the export machinery, or if different members of the export machinery recognize different substrate classes. Solving the composition and exact function of the export apparatus will help to understand the missing details in needle length control.

For *Shigella*, a similar model for needle length control was suggested [132]. Replacing *spa32* by *Y. enterocolitica yscP* led to needles of controlled length, but longer than in the wild type *Shigella* strain [132]. This fits with the molecular ruler hypothesis: Spa32 consists of 292 residues resulting in needles of 45 +/- 7 nm length, compared to YscP which consists of 515 residues and determines needle length at 65 +/- 10 nm in *Yersinia* and 54 +/- 13 nm in *Shigella* [132]. In contrast, the inner rod model was suggested [123] for needle length control in *Salmonella*

proposing a different function for InvJ, the YscP homolog in *Salmonella*. The data reported in this thesis, especially the direct correlation between YscP length and needle length, can exclude this model of length control for *Yersinia*.

Appendix

Additional results

Insertions in the central part of YscP lead to longer needles

In a previous work, insertions were made between the two export signals at residues 49 and 50 of YscP (site I, Figure A1 A), and an increase in needle length was observed [53]. No insertion was made between residues 137 and 405. The ruler hypothesis predicts that insertions of the same polypeptide at different sites of YscP would lead to the same needle length. To test this, restriction sites were engineered (after codons 186 (site II), 250 (site III) or 390 (site IV)) and either the ruler region of YscP encoding residues 214-374 was duplicated by insertion or the ruler region of its flagellum homolog FliK (amino acids (aa) 151-270) was inserted in either of these three sites (Figure A1 A). Although the extra region was inserted at three different sites, the two sets of recombinant proteins had the same number of residues (i.e., 686 or 645). The inserted domains were the same as the ones inserted earlier after codon 49 [53]. The eight different recombinant genes, expressed downstream from the pBAD promoter were introduced into *yscP* knockout bacteria and needles were measured. As predicted from the ruler hypothesis, needles from clones with insertions at sites I, II or III had the same median length (105 or 106 nm for YscP insertions and 93 or 94 for FliK insertions, Figure A1) and a similar small standard deviation indicating a functional length control. Moreover, YscP mutants with insertions from the FliK protein were able to control needle length to the same degree as YscP mutants with YscP insertions. These data strengthen the ruler model.

In contrast, the clones with the insert at position 390 (site IV) resulted in needles with variable length. This suggests that the insert altered the functionality of YscP presumably due to the close vicinity of the T3S4 domain (aa 405-500; Figure A1 B).

To verify whether the value of 105 nm correlates with the length values determined by other YscP variants, wild type (wt) needles (YscP = 515 aa) and needles assembled by bacteria endowed with the double deletion mutant pCA20 (YscP₃₈₈ = 388 aa) were measured. An extra-long variant of YscP was engineered by

inserting residues 151-270 of FliK, into site III and the YscP repeat (residues 214-374) into site I (805 aa in total). As shown in Figure A1 C, there was a good linear correlation between needle length and the number of residues in YscP, with an increment of 2.1 Å per residue (Figure A1 C).

Figure A1

Effect of insertions and deletions within YscP on the needle length.

A. Schematic representation of YscP showing the four engineered restriction sites for insertions. The table shows the inserted or deleted material, the site of insertion, the total number of residues in YscP and the length of the needles.

B. Histograms of length measurements. s.D., standard deviation; n, number of measured needles

C. Correlation of needle length with the total number of residues in YscP. Note that some points are completely overlapping. The unregulated length of the needles controlled by the yscP variants encoded by pSTW16 and pSTW17 are not plotted.

The needle lengths of wt and previously published constructs (pLJ6, pLJ18, pLJ19, pCA20) were slightly different from the values published in a previous work [53] as a result of a better calibration of the microscope. Taken together, these data reinforce the observation that the length of the needle is a direct function of the number of residues in the central region of YscP (aa 36-380).

How many rulers are secreted by the *Yersinia* injectisome?

Insertion of Penicillin Binding Protein into the ruler domain

One attempt to address the question of how many YscP proteins are secreted per injectisome was the labelling of exported YscP with a radioactive marker. The advantage of this method lies in its accuracy due to the sensitivity of the quantification. A prerequisite is the constant labelling of that YscP with the same amount of radioactivity. Since it was shown that large insertions in YscP result in a functional protein ([53]; Figure A1), a hybrid consisting of YscP and a Penicillin Binding Protein (PBP) inserted into the ruler region should allow quantification of secreted YscP by tritium labelled Penicillin. PBP from *Streptomyces* K15 was inserted between export signals 1 and 2 of YscP into pCA23 using restriction sites NotI/XbaI (pSTW18) or into the repeat region of YscP using restriction sites ClaI/Spel of pSTW4 (pSTW23).

The two YscP mutants were transformed into a $\Delta yscP$ *Y. enterocolitica* strain and tested for complementation concerning Yop secretion, YscP export and needle length control. Both mutants had wt levels of Yop secretion. However, the needle length was less controlled (standard deviation: ~ 30 nm) probably due to the weak export level of the fusion proteins. Thus, the YscP-PBP fusion proteins were not suitable to quantitatively study the amount of exported YscP per injectisome needle.

Quantification of secreted YscP and YscF

A second attempt to address the above question was the determination of the number of YscP molecules released in the culture supernatant by quantitative immunoblotting and the number of needles present at the surface of the bacteria. There are, however, three major caveats. First, only exported YscP and YscF molecules must be assayed to avoid overestimation due to the intrabacterial pool of non-exported proteins. This implies that needles need to be quantitatively shaved from the bacterial surface. Second, although the models imply that all YscF subunits polymerize after export, this has never been demonstrated experimentally. Third, it was reported that exported molecules of YscP remain attached at the bacterial surface [125]. Finally, it is unknown if there is unspecific excess export of YscP. This

attempt is therefore only able to show how many rulers are exported per injectisome needle, but not to answer the question of how many rulers are needed to determine the length of one needle.

Figure A2

Purification of His₆-tagged YscP variants.

Purification of YscP₆₈₀ (pSTW29), YscP wt (pLJ14) and YscP₃₈₈ (pSTW28) from inclusion bodies under denaturing conditions using 8 M urea. The uninduced (U), induced (I), washing (W) and elution (E) fractions from the nickel-sepharose column were analyzed by SDS-PAGE (left panels). The elution fractions were subjected to a size exclusion column and elution fraction were analyzed by Coomassie-stained SDS-PAGE (right panels).

For the calculation of the ratio of secreted YscP per injectisome needle, the exact amounts of extracellular YscP and extracellular YscF must be quantified. The latter is needed for the calculation of the number of injectisome needles. Purified YscP and

YscF serve as protein standards for quantification of these proteins obtained from the culture supernatant.

YscP₃₈₈ (from pCA20), YscP wt (from pLJ6) and YscP₆₈₀ (from pLJ19) were cloned with a N-terminal His₆-tag downstream of the pBAD promoter (see Table I). Expression of the His₆-tagged proteins in *E. coli* Top10 strains was induced with 0.2% arabinose and bacteria were harvested after 4 hours at 37 °C. Insoluble YscP proteins (data not shown), were purified from inclusion bodies under denaturing conditions using 8 M urea (Figure A2, left panel). Elution fractions # 3 from wt YscP, # 3 from YscP₆₈₀ and # 4 from YscP₃₈₈ were applied to a size exclusion column (Figure A2, right panel). Concentrations from fractions 9 (YscP wt = 213.8 µg/mL), 10 (YscP₃₈₈ = 131.4 µg/mL) and 7 (YscP₆₈₀ = 260.6 µg/mL) were calculated using BSA as protein standard in a Bradford assay.

YscF was purified as GST-tagged fusion protein followed by cleavage of the GST-tag with thrombin (kindly provided by Isabel Sorg; data not shown). The concentration of purified YscF was determined by UV spectroscopy (1.40 mg/mL, data not shown).

Because of the attachment of YscP to the bacterial surface, the bacteria were “shaved” to solubilize YscP from the surface, and to break all the needles from the surface. The shearing was done mechanically by re-suspending the bacterial pellet 40 times in 100 µL buffer using a P-200 pipette. Tris-buffer was tested for shaving of the bacteria at varying pH (6-7), detergent concentrations (Nonidet P 40 substitute (NP 40): 0.01-1%) and salt concentrations (NaCl) under secreting and non-secreting conditions (Figure A3 A and B, respectively). As a control, the supernatant and shearing fractions were tested for cell lysis by immunoblotting using antibodies against the intracellular protein YscJ. As shown in Figure A3 A Tris-buffer containing 0.5% NP 40 at pH 7 (SN + Ca²⁺ sample 5) were optimal conditions for complete removal of the needles from the bacterial surface.

Figure A3

Shaving YscP and injectisome needles from the bacterial surface of *Y. enterocolitica*.

A. Supernatant fractions (SN) and total cell (TC) fractions of *Y. enterocolitica* E40 wt (pYV40) or *Y. enterocolitica* E40 $\Delta yscP$ (pLJ4036). Cultures were grown in secretion conditions ($-Ca^{2+}$). Bacterial pellets were treated like usual (see Method section) (1) or sheared mechanically using different buffers: Tris-HCl pH 7, 0.01% NP 40, 100 mM NaCl (2); Tris-HCl pH 6 (3); Tris-HCl pH 6, 1% NP 40 (4); Tris-HCl pH 7, 0.5% NP 40 (5); Tris-HCl pH 7, 1% NP 40 (6). Supernatant and shearing fractions were combined. Supernatant (SN) and total cell (TC) fractions were analyzed by immunoblot using anti-YscP, anti-YscJ and anti-YscF antibodies.

B. Supernatant fractions (SN) and total cell (TC) fractions of the same cultures as in (A). Cultures were grown in non-secretion conditions ($+Ca^{2+}$). Bacterial pellets were treated like described for (A). Supernatant (SN) and total cell (TC) fractions were analyzed by immunoblot using anti-YscP, anti-YscJ and anti-YscF antibodies.

C. Supernatant fractions (SN) and total cell (TC) fractions of *Y. enterocolitica* E40 wt (pYV40). Culture was grown in non-secretion conditions ($+Ca^{2+}$). Bacterial pellets were sheared mechanically using different buffers: Tris-HCl pH 7, 0.01% NP 40, 100 mM NaCl (buffer 1); Tris-HCl pH 7, 0.1% NP 40, 200 mM NaCl (buffer 2); Tris-HCl pH 6, 0.5% NP 40 (buffer 3). The shearing was done three times. Supernatant (SN), shearing (S) and total cell (TC) fractions were analyzed by immunoblot using anti-YscP, anti-YscJ and anti-YscF antibodies.

Under these conditions, partial lysis of the bacteria was observed by a faint band for the internal YscJ. Considering this control and the fact that the quantification experiment should be carried out in non-secreting conditions (only assembly of the type III secretion system), the best buffer to shave bacteria was Tris-buffer 2 containing 100 mM NaCl, and 0.01% NP 40 at pH 7 (Figure A3 B). To improve shaving, the number of shearing steps was increased to completely recover YscP and YscF from the bacterial surface.

As shown in Figure A3 C, after the third shearing step bands for YscF and YscP were still detected by immunoblotting, without observing cell lysis. In the experiment shown in Figure A3 C buffer 5 was further adjusted and the best result was obtained using a Tris-buffer with 200 mM NaCl, 0.1% NP 40 at pH 7 (Figure A3 C). In the fifth shearing supernatant fraction YscF and YscP could not be detected. However, a control to prove that all YscP and YscF was completely shaved from the bacterial surface is not available. The conditions used for the quantification experiment were therefore shearing the bacterial pellet five times in 100 μ L of shearing buffer (200 mM NaCl, 0.1% NP 40, Tris-HCl pH 7) and combining the supernatant fraction with the five shearing fractions.

Y. enterocolitica wt, *Y. enterocolitica* LJ4022 (YscP₃₈₈) or *Y. enterocolitica* LJM4001 (YscP₆₈₀) were grown at room-temperature in BHI + Ca²⁺ and expression of the type III system was induced by a temperature shift to 37 °C. Bacteria were harvested 2 hours after the temperature shift and samples were prepared as described before. The samples and different amounts of purified YscF and YscP were subjected to a 15% SDS-PAGE and analyzed by immunoblotting using antibodies against YscF and YscP (Figure A4 A). Immunoblots were detected using films, scanned and analyzed using software GelEval 1.21b (demo version, FrogDance software), immunoblots obtained with the Fuji LAS 4000 imager were analyzed by Fujifilm Multi Gauge software. The calculation was performed according to:

$$YscP/needle = (ng\ YscP * (molecules\ YscF/needle) * MW\ [YscF]) / (MW\ [YscP] * ng\ YscF)$$

Several quantification assays were performed, but the resulting number of secreted YscP per injectisome needle differed with an average and standard deviation of 22 ± 21 YscP per needle.

Considering the data obtained in Result Section “One ruler per needle”, this method proved unsuitable for determining the correct number of secreted YscP per needle.

Figure A4

Quantitative immunoblot of detached YscP and injectisome needles.

Supernatant fractions (SN) of *Y. enterocolitica* E40 *yscP*₆₈₀ (pLJM4001), *Y. enterocolitica* E40 wt (pYV40) and *Y. enterocolitica* E40 *yscP*₃₈₈ (pLJ4022). Cultures were grown in non-secretion conditions (+Ca²⁺). Bacterial pellets were sheared five times mechanically in shearing buffer (Tris-HCl pH 7, 0.1% NP 40, 200 mM NaCl). The shearing fraction were combined with the supernatant fraction. The supernatant (SN) fractions were analyzed by immunoblotting using anti-YscP and anti-YscF antibodies. Different amounts of purified YscF and YscP variants were used as protein standard.

YscU_{N263Q}

In our previous work, we could show that the transmembrane protein YscU is involved in substrate recognition and a cleavage site mutant YscU_{N263A} is impaired in exporting translocators and secretion of YscP [130]. Due to the impaired secretion of YscP needle length regulation was diminished which could be rescued by over-expression of the molecular ruler YscP. In a further study the crystal structure of the cytoplasmic domain of YscU was deciphered and the auto-cleavage reaction was analyzed [158]. In this study several YscU point-mutations were engineered and a new phenotype was observed. The cleavage deficient mutant YscU_{N263Q} expressed *in trans* in a *yscU* knockout strain could not secrete LcrV and moreover, YscP export was reduced. Nevertheless needles were regulated, but longer than wt needles. The cleavage of this mutant could not be analyzed *in vivo* and therefore the mutation was introduced in the wt bacteria using homologous recombination. As shown in Figure A5 A Yop secretion by YscU_{N263Q} was similar to the secretion pattern of the cleavage site mutant YscU_{N263A} (under physiological and over-expression conditions). Secretion of effector proteins was comparable to wt levels, whereas the translocators were missing. Cleavage of YscU was analyzed by immunoblotting, as shown in Figure A5 B. Since YscU is a transmembrane protein and is probably present in a very low copy number, it was not possible to detect YscU wt in its cleaved conformation. Only when expressed *in trans* a faint band of the non-cleaved YscU was visible probably due to over-expression of the protein. In contrast, for both YscU mutants (YscU_{N263A} and YscU_{N263Q}) a band of the full-length protein was visible, even under physiological conditions (Figure A5 B). When YscU mutants were expressed *in trans* even the alternative cleaving products could be observed like published in Sorg *et al.*, 2007. Both mutations showed the same pattern suggesting that also the YscU_{N263Q} mutant was not cleaved *in vivo*. Furthermore, export levels of YscP and LcrV were analyzed by immunoblotting (Figure A5 B). Again, the YscU_{N263Q} mutant showed the same phenotype as the cleavage site mutant YscU_{N263A}. Export of LcrV was diminished and secretion of YscP was reduced when mutants were expressed *in trans*, whereas similar levels of YscP were secreted when the mutants were expressed downstream of the native promoter. Needle length was analyzed as

shown in Figure A5 C. The median of needles did not differ (80 and 81 nm), independent of YscU_{N263A} expressed *in trans* under the pBAD promoter or under its native promoter. The standard deviation was, however, higher when YscU_{N263Q} was expressed under its native promoter.

Figure A5

Analysis of a “new” phenotype observed for YscU_{N263Q} over-expression.

A. Yops secreted by *Y. enterocolitica* E40 wt (pYV40), *Y. enterocolitica* E40 yscU_{N263A} (pISO4007), *Y. enterocolitica* E40 yscU_{N263Q} (pSTW4003), *Y. enterocolitica* E40 ΔysecU (pLY4001) and *Y. enterocolitica* E40 ΔysecU (pLY4001) mutant bacteria over-expressing YscU (pLY7), YscU_{N263A} (pSTW7), or YscU_{N263Q} (pISOA167) *in trans* from the pBAD promoter. Supernatant fractions (SN) were analyzed by SDS-PAGE.

B. Supernatant fractions (SN) and total cell (TC) fractions of the same cultures as in (A) were analyzed by immunoblot with anti-YscP, anti-LcrV and anti-YscF antibodies.

C. The histograms of needle length measurements of bacteria expressing YscU_{N263Q}. s.D., standard deviation; n, number of measured needles.

These preliminary data need to be confirmed. Nevertheless, it seems as if there is no difference between the cleavage site mutant YscU_{N263A} and YscU_{N263Q}. Needle of the latter mutant are shorter than needles from the cleavage site mutant YscU_{N263A} (125 nm; [130]) but regulation is not very tight when compared to wt (67 +/- 10 nm).

YscP - molecular ruler or molecular timer?

In previous work we were able to show a direct correlation between the length of YscP and the needle length [53, 157]. There are at least two possible explanations for these results. Either YscP acts as a molecular ruler where YscP would be secreted and partially fold during needle assembly. When the C-terminal domain of YscP gets in contact with the export apparatus, the T3S4 domain would be in the right position to switch substrate specificity and thereby stop needle elongation. Or YscP acts as a molecular timer and it is the time YscP needs to be exported which determines the needle length. In *Shigella* and *Salmonella*, over-expression of the needle subunit (MxiH or PrgI, respectively) leads to elongated needles [31, 123]. These results are in favour of the timer model, if over-expression would result in enhanced/faster export of the needle subunit. However, over-expression of the needle subunit YscF alone did not give elongated injectisome needles in *Y. enterocolitica*, whereas over-expression of the needle subunit YscF together with its chaperones YscE and YscG, and two other small secreted proteins in this operon (YscI and YscH) led to elongated needle length (Isabel Sorg, unpublished data). To test if the timer model applies to YscP, over-expression and decreased expression of YscEFGHI was investigated. A plasmid carrying *yscEFGHI* downstream of the pBAD promoter was transformed into *Y. enterocolitica* E40 wt or a Δ *yscEFGHI* strain. For over-expression of YscEFGHI, expression was induced using 0.5% arabinose in the wt background (Figure A6). For decreased expression levels of YscEFGHI, the plasmid was induced with 0-0.2% arabinose in the Δ *yscEFGHI* strain. Inducing the expression of YscEFGHI with 0.2% arabinose gave levels of YscF and YscI as in wt bacteria (data not shown). Therefore needles were analyzed using only 0.1% arabinose, and induction was done either once at the temperature shift to 37 °C or twice at the temperature shift and 2 hours after growing bacteria at 37 °C (standard condition). As shown in Figure A6 B export of YscP and export of YscI were decreased when the expression of YscEFGHI was induced at low levels, compared to the wt. In comparison, expression levels of YscP were similar in all strains (Figure A6 B). Only a faint band of YscF was detectable in the total cell (TC) fractions when the expression of YscEFGHI was induced at low levels, compared to the wt.

Analysis of needle length confirmed that over-expression of YscEFGHI leads to elongated needles (data not shown). However, with decreased expression of YscEFGHI only few needles of wt length were observed. These results exclude YscP being a molecular timer as described before. The elongated needle length observed upon over-expressing YscEFGHI might result from a delayed export stop of early substrates, due to the massive over-expression of the small Yscs.

Figure A6

Over-expression of YscEFGHI does influence needle length control.

A. Yops secreted by *Y. enterocolitica* E40 wt (pYV40), *Y. enterocolitica* E40 wt (pYV40) bacteria over-expressing YscEFGHI (pISO147) *in trans* from the pBAD promoter, *Y. enterocolitica* E40 ΔyscEFGHI (pISO4017) and *Y. enterocolitica* E40 ΔyscEFGHI (pISO4017) mutant bacteria over-expressing YscEFGHI (pISO147) *in trans* from the pBAD promoter. The amount of arabinose used for protein expression is indicated. Arabinose was only added once (at the temperature shift), when indicated with an asterisk (*). Supernatant fractions (SN) were analyzed by SDS-PAGE.

B. Supernatant fractions (SN) and total cell (TC) fractions of the same cultures as in (A) were analyzed by immunoblot with anti-YscP, anti-YscF, and anti-YscI antibodies. The amount of arabinose used for protein expression is indicated. Arabinose was only added once (at the temperature shift), when indicated with an asterisk (*).

The [tāl] of YscP

Agrain *et al.* showed that YscP has a tail (aa 500-515) which is conserved in the YscP family and predicted to form a α -helix [110]. A YscP $_{\Delta 501-515}$ mutant (over-expressed from pLJC12) was shown to complement the $\Delta yscP$ strain for Yop secretion [110]. YscP export has not been shown and needle length analysis revealed that needles are regulated but with a high standard deviation (45 ± 44 nm, [110]). Moreover, needles from these mutants were shorter than expected for a 15 amino acid deletion. It must be noted that the needle length values for wt and other constructs measured in this study were slightly different from the values published previously [53] as a result of a better calibration of the microscope.

Since all the results published so far resulted from an over-expression of the YscP $_{\Delta 501-515}$ mutant *in trans*, the deletion was introduced into the wt allele of YscP on the pYV plasmid. A stop codon was introduced after amino acid 499 using homologous recombination to obtain the mutant YscP $_{\Delta Tail}$ ($\Delta 500-515$). The phenotype resulting from this mutation, was compared to the phenotype observed from the over-expression of this mutant downstream of the pBAD promoter. As shown in Figure A7 A the pattern of Yop secretion was different under physiological conditions. Over-expression of YscP $_{\Delta 501-515}$ resulted in a complete complementation of a $\Delta yscP$ strain (concerning Yop secretion) as it was shown for wt YscP. In contrast, when YscP $_{\Delta 500-515}$ was expressed under its native promoter only effector Yops were secreted but not the translocators (Figure A7 A). This secretion pattern reminded of the phenotype described for the YscU cleavage site mutant YscU $_{N263A}$ (Results chapter; [130]) which suggested a role for YscU in substrate recognition. Immunoblotting using antibodies against YopB, YopD (data not shown) and LcrV (Figure A7 B) revealed a dramatically reduced export of the translocators compared to the wt. Moreover and most strikingly, secretion of YscP was also impaired when YscP $_{\Delta 500-515}$ was expressed under its native promoter, but not when over-expressed *in trans* (Figure A7 B). Analyzing needle length control showed regulated needles, though not to wt level, with a median and standard deviation of 70 ± 36 nm (wt: 66 ± 7 nm, Figure A7 C) when YscP $_{\Delta 501-515}$ is over-expressed. In contrast, expression of

YscP $_{\Delta 500-515}$ downstream of its native promoter resulted in uncontrolled needle length, however needles were not longer than ~ 300 nm.

Figure A7

Effect of deleting the tail of YscP on the needle length and substrate switching.

A. Yops secreted by *Y. enterocolitica* E40 wt (pYV40), *Y. enterocolitica* E40 $\Delta yscP$ (pLJ4036), *Y. enterocolitica* E40 $yscP_{\Delta tail}$ (pSTW4002), *Y. enterocolitica* E40 $yscU_{N263A}$ (pISO4007) and *Y. enterocolitica* E40 $\Delta yscP$ (pLJ4036) mutant bacteria over-expressing YscP (pLJ6) or YscP $_{\Delta tail}$ (pLJC12) *in trans* from the pBAD promoter. The amount of arabinose used for protein expression is indicated.

B. Supernatant fractions (SN) and total cell (TC) fractions of the same cultures as in (A) were analyzed by immunoblot with anti-YscP and anti-LcrV antibodies.

C. The histograms of length measurements. s.D., standard deviation; n, number of measured needles.

To investigate whether the YscP $_{\Delta 500-515}$ mutant bacteria were able to switch substrate specificity from early substrates (e.g., YscF) to intermediate substrates (translocators) a YopE-LcrV fusion [130] was used as reporter construct (Figure A8). The export signal of the effector YopE was fused to the N-terminus of LcrV [130] and export of the hybrid was analyzed in YscP $_{\Delta 500-515}$ and in YscU $_{N263A}$ mutant bacteria. As shown in Figure A8 a protein of the expected size was detected by Coomassie-stained

SDS-PAGE of the supernatant fractions. The identity of the protein was confirmed by immunoblotting using anti-LcrV antibodies (Figure A8). In contrast to the YopE-hybrid protein, LcrV alone was not exported in the YscP $_{\Delta 500-515}$ and the YscU $_{N263A}$ mutants (Figure A8). These data suggest that the loss of LcrV export is due to a defect in recognition of LcrV as export substrate.

Figure A8

YopE $_{1-15}$ LcrV is exported by *Y. enterocolitica* yscU $_{N263A}$ and yscP $_{\Delta 500-515}$ mutant bacteria.

Yops secreted by *Y. enterocolitica* E40 wt (pYV40), *Y. enterocolitica* E40 yscU $_{N263A}$ (pISO4007) and *Y. enterocolitica* E40 yscP $_{\Delta 500-515}$ (pSTW4002) mutant bacteria over-expressing LcrV (pPB42) or YopE $_{1-15}$ LcrV (pISOA132) *in trans* from the pBAD promoter. The position of the YopE $_{1-15}$ LcrV and LcrV proteins are indicated. Supernatant fractions (SN) were analyzed by immunoblot with anti-LcrV antibodies (lower blot).

To test if over-expression of the tail peptide could rescue the phenotype observed for the YscP $_{\Delta 500-515}$ mutant, the tail of YscP, yscP $_{497-515}$ or his $_6$ -yscP $_{497-515}$ was cloned downstream of the pBAD promoter and expressed *in trans* in the *Y. enterocolitica* E40 wt strain. An effect on expression and secretion level of YscP was not observed by immunoblotting with anti-YscP antibodies (Figure A9 A).

Figure A9

Effect of over-expression of the YscP tail peptide in different backgrounds.

A. Supernatant fractions (SN) and total cell (TC) fractions of *Y. enterocolitica* E40 wt (pYV40), *Y. enterocolitica* E40 wt (pYV40) bacteria over-expressing YscP₄₉₇₋₅₁₅ (pSTW49) or His₆-YscP₄₉₇₋₅₁₅ (pSTW50) *in trans* from the pBAD promoter or *Y. enterocolitica* E40 wt (pYV40) transformed with an empty pBAD vector. Supernatant (SN) and total cell (TC) fractions were analyzed by immunoblot using anti-YscP antibodies.

B. Total cell (TC) fractions of *Y. enterocolitica* E40 wt (pYV40), *Y. enterocolitica* E40 wt (pYV40) bacteria over-expressing YscP₄₉₇₋₅₁₅ (pSTW49) or His₆-YscP₄₉₇₋₅₁₅ (pSTW50) *in trans* from the pBAD promoter or *Y. enterocolitica* E40 wt (pYV40) transformed with an empty pBAD vector; *Y. enterocolitica* E40 ΔyscP (pLJ4036), *Y. enterocolitica* E40 ΔyscP (pLJ4036) bacteria over-expressing YscP₄₉₇₋₅₁₅ (pSTW49) or His₆-YscP₄₉₇₋₅₁₅ (pSTW50) *in trans* from the pBAD promoter or *Y. enterocolitica* E40 ΔyscP (pLJ4036) transformed with an empty pBAD vector; *Y. enterocolitica* E40 yscP_{Δtail} (pSTW4002), *Y. enterocolitica* E40 yscP_{Δtail} (pSTW4002) bacteria over-expressing YscP₄₉₇₋₅₁₅ (pSTW49) or His₆-YscP₄₉₇₋₅₁₅ (pSTW50) *in trans* from the pBAD promoter or *Y. enterocolitica* E40 yscP_{Δtail} (pSTW4002) transformed with an empty pBAD vector; *Y. enterocolitica* E40 yscUN_{263A} (pISO4007), *Y. enterocolitica* E40 yscUN_{263A} (pISO4007) bacteria over-expressing YscP₄₉₇₋₅₁₅ (pSTW49) or His₆-YscP₄₉₇₋₅₁₅ (pSTW50) *in trans* from the pBAD promoter or *Y. enterocolitica* E40 yscUN_{263A} (pISO4007) transformed with an empty pBAD vector. Total cell (TC) fractions were analyzed by immunoblot with anti-YscP antibodies.

However, expression of the tail peptide YscP₄₉₇₋₅₁₅ could not be detected, neither by immunoblotting, nor by a silver-stained SDS-PAGE (data not shown). This is most likely due to the very small size of the peptide (19 aa). Expression of YscP₄₉₇₋₅₁₅ or His₆-YscP₄₉₇₋₅₁₅ in the ΔyscP strain, the yscP_{Δ500-515} or the yscUN_{263A} mutants did

also not lead to an effect on expression or export level of YscP wt (Figure A9 B, data not shown).

Since the mutant YscP₄₉₇₋₅₁₅ can not be exported by the type III secretion machinery when expressed under its native promoter, the YscP tail might either be important for the correct recognition of YscP or for the correct interaction with its binding partner to switch substrate specificity as suggested for FliK and FlhB [109]. Therefore, the YscP_{Δ500-515} (YscP_{Δ500-515}) mutant was included in the interactions studies with YscU as described below.

Interactions (and) partners

YscI - polymerization-cap or rod?

YscI is a 12.7 kDa protein which is exported by the type III secretion system of *Yersinia*. YscI is needed for needle assembly and is secreted in amounts proportional to YscF ([161], Group Cornelis unpublished data). The homolog protein in *Salmonella typhimurium* is PrgJ, which is proposed to form the inner rod of the basal body [37]. In *Shigella* it is still under debate, whether the PrgJ homolog MxiI is the inner rod protein [162] or forming a cap-like structure on top of the needle [30]. MxiI is supposed to be the functional homolog of FlgD the flagellar hook cap protein [100]. Wood *et al.* [161] propose YscI to be the inner rod protein based on a sequence alignment (with YscF and YscI family members) and suggest that the formation of the inner rod is critical for substrate specificity switching and that YscU and YscP use their effects on substrate export by controlling the secretion of YscI. This model is based on the finding that certain point mutations in YscI secrete Yops but show a severe defect in needle formation. In the absence of YscP these mutants are able to assemble needles, but are unable to secrete Yops. Wood *et al.* [161] also show that YscI export is increased in a *yscP* knockout strain but that mutations in the cytoplasmic domain of YscU can rescue this phenotype.

Since Wood *et al.* [161] did not analyze needle formation in the YscI mutants by electron microscopy, we decided to engineer two of the published mutants and analyze needle formation and length. YscI_{Q84A} and YscI_{L96A} were engineered by site directed mutagenesis and expressed *in trans* under the pBAD promoter in a Δ yscI strain. As shown in Figure A10 A, YscI wt expressed *in trans* was able to complement the Δ yscI strain concerning Yop secretion (Figure A10 A), export of YscP, LcrV and YscI (Figure A10 B) and needle length control (Figure A10 C). In contrast, both YscI mutants only partially complemented the deletion mutant for Yop secretion. Export of effector Yops was comparable to wt levels, whereas secretion of translocators was dramatically decreased (Figure A10 A). Secretion of YscP and LcrV was not detectable by immunoblotting (Figure A10 B) in both mutants, whereas export of YscI was reduced in YscI_{Q84A} but not in YscI_{L96A}. Length measurement of the injectisome needle showed that the YscI_{Q84A} mutant assembled needles which

were controlled, but with a higher median and a slightly increased standard deviation (Figure A10 C). This might be due to the decreased export of YscP.

Figure A10

YscL_{Q84A} and YscL_{96A} mutant proteins are not exported but do not inhibit needle length control.

A. Yops secreted by *Y. enterocolitica* E40 wt (pYV40), *Y. enterocolitica* E40 Δ yscI (pKEM4001) and *Y. enterocolitica* E40 Δ yscI (pKEM4001) mutant bacteria over-expressing YscI (pKEM4), YscL_{Q84A} (pSTW55), or YscL_{96A} (pSTW56) *in trans* from the pBAD promoter. Supernatant fractions (SN) were analyzed by SDS-PAGE.

B. Supernatant fractions (SN) of the same cultures as in (A) were analyzed by immunoblot with anti-YscP, anti-LcrV and anti-YscI antibodies.

C. The histograms of length measurements and transmission electron micrograph. s.D., standard deviation; n, number of measured needles.

In contrast to Wood *et al.* [161], in our hands both mutants were able to assemble injectisome needles, but were impaired in the secretion of translocators. Moreover, YscL_{Q84A} secretion was dramatically reduced while needles were still assembled. In a Δ yscI strain no needle formation was observed.

To analyze needle formation in a Δ yscP background, a yscI/yscP double knockout strain was engineered using allelic exchange to delete yscP in the Δ yscI strain. As shown in Figure A11 A, no Yop secretion was observed when YscP is deleted. Immunoblotting revealed that YscI wt as well as the two YscI mutants were expressed in a Δ yscP background (Figure A11 B) whereas only YscL_{Q84A} was not

secreted into the culture supernatant (Figure A11 B). LcrV export was completely diminished in the absence of YscP and YscF was only detectable in the supernatant of YscI wt and YscI_{L96A} bacteria, suggesting that these two strains are able to assemble needles, whereas YscI_{Q84A} is impaired in needle formation (Figure A11 B). The absence of needles in the YscI_{Q84A} strain was confirmed by electron microscopy. The double deletion $\Delta yscI/\Delta yscP$ complemented with either YscI wt or YscI_{L96A} resulted in extra-long needles like observed in a $\Delta yscP$ strain [53]. Taking together, these results show that YscI_{Q84A} with reduced export can assemble needles in the presence of YscP, but not in its absence.

Figure A11

The YscI_{Q84A} mutant is not able to assemble needles in a $\Delta yscP$ background.

A. Yops secreted by *Y. enterocolitica* E40 wt (pYV40), *Y. enterocolitica* E40 $\Delta yscI$ (pKEM4001), *Y. enterocolitica* E40 $\Delta yscI$ (pKEM4001) mutant bacteria over-expressing YscI (pKEM4), YscI_{Q84A} (pSTW55), or YscI_{L96A} (pSTW56) *in trans* from the pBAD promoter, *Y. enterocolitica* E40 $\Delta yscP$ (pLJ4036), *Y. enterocolitica* E40 $\Delta yscI/\Delta yscP$ (pSTW4005) and *Y. enterocolitica* E40 $\Delta yscI/\Delta yscP$ (pSTW4005) mutant bacteria over-expressing YscI (pKEM4), YscI_{Q84A} (pSTW55), or YscI_{L96A} (pSTW56) *in trans* from the pBAD promoter. Supernatant fractions (SN) were analyzed by SDS-PAGE.

B. Supernatant fractions (SN) and total cell (TC) fractions of the same cultures as in (A) were analyzed by immunoblot with anti-YscP, anti-LcrV, anti-YscF, and anti-YscI antibodies.

Interaction studies

Assuming the ruler model as proposed by Journet *et al.* [53] is correct, YscP would have to interact with other proteins in order to fulfill its function. These proteins are most likely located at the base of the basal body and at the tip of the growing needle. Since a ΔcrV mutant does assemble wt needles [157] the tip forming protein LcrV can be excluded as binding partner. However, several small Ysc proteins (YscI, YscH, YscX and YscO) are secreted as early substrates but to date none of these proteins has a function assigned. Another possibility is that YscP might form an umbrella like structure at the tip of the growing needle which would serve as a polymerization cap or anchor to sense the distal needle end. In this model a binding partner at the distal needle end would not be needed. Polymerization of the needle could be the driving force to export YscP in this model of needle length control. Despite that, a binding partner at the base of the basal body remains a prerequisite to switch substrate specificity. In the flagellum, FliK was inferred to interact with the soluble carboxyl-terminal domain of FlhB (FlhBc) [116]. This interaction plays a crucial role in the switch from hook to filament secretion in the flagellum system. Botteaux *et al.* [132] showed for *Shigella flexneri* by pull down experiments that the YscP homolog Spa32 interacts with the YscU homolog Spa 40. These data together with the results by Sorg *et al.* [130] showing a role for YscU in substrate recognition, suggest that YscP and YscU do interact in *Y. enterocolitica*. This has never been shown experimentally. Two different attempts were chosen to test interaction between YscU and YscP which could later serve for identification of other binding partners of YscP. The YscP Δtail (YscP $\Delta\text{500-515}$) mutant was included in this study since the mutant can not be exported by the type III secretion machinery, and the YscP tail might either be important for the correct recognition of YscP or for the correct interaction with its binding partner to switch substrate specificity as suggested for FliK [109].

Retardation column

First, a GST-tagged protein (YscU) immobilized to a matrix was incubated with either the supernatant fraction of a bacterial culture secreting YscP, or purified proteins (YscP or YscU). Retardation of the untagged protein would suggest that several

transient interactions take place and slow down the flow of the untagged protein [163]. So far, purification of YscP was only possible under denaturing conditions, in 8 M urea. Nevertheless, a GST-tagged YscP fusion leads to detectable amounts of soluble YscP after cleavage of the tag with PreScission protease. Since YscU (and its homologs) undergoes an autoproteolytic cleavage between N263 and P264 [116, 158, 160, 164, 165] the non cleavable mutant YscU_{N263A} was chosen for these interaction studies.

When GST-YscU₂₁₁₋₃₅₄ (from pISO116) or GST-YscU_{211-354,N263A} (from pISO117) was immobilized to glutathione sepharose beads and incubated with either supernatant from a *Y. enterocolitica* E40 wt strain or from a Δ yscP strain complemented with pLJC12 (secretion of YscP _{Δ tail}, see A [tā] of YscP) bands for YscP could not be detected by immunoblotting of the elution fraction (data not shown). This could be due to a low concentration of YscP in the supernatant fraction. Therefore the experiments were repeated with purified proteins, at higher concentrations and in absence of possible disturbing contaminants. Figure A12 shows an assay where GST-tagged YscP or YscP _{Δ tail} was immobilized to glutathione sepharose beads and incubated with purified YscU₂₁₁₋₃₅₄ or YscU_{211-354,N263A}. Figure A12 (right panel) shows the absence of detectable amounts of YscU by immunoblotting with anti-YscU antibodies for YscU₂₁₁₋₃₅₄. However, for the non cleavable YscU_{211-354,N263A}, bands for YscU were detected in the washing fractions and in the elution fractions (glutathione concentrations, 0-10 mM). YscU_{211-354,N263A} was detected by immunoblotting when incubated with GST alone, but this background was negligible when compared to the intensity of the bands detected when GST-YscP wt was immobilized to the matrix (Figure A12). The bands detected for YscU_{211-354,N263A} when YscP _{Δ tail} was immobilized to the beads were less intense than for GST-YscP (Figure A12). These results suggest that YscP _{Δ tail} has a defect in binding to YscU_{N263A}. However, these preliminary results need to be confirmed. Moreover, these data only suggest an impaired binding between YscP _{Δ tail} and YscU_{N263A}. A difference in binding between YscP _{Δ tail} and YscU compared to YscP and YscU remains to be demonstrated.

Figure A12

YscU_{N263A} is retarded on a YscP-labelled column.

GST-tagged YscP (pSTW19), YscP_{Δtail} (pSTW57) or GST (pGEX-6P-1) alone are immobilized to glutathione sepharose beads and incubated with either purified YscU₂₁₁₋₃₅₄ (pISO116) or purified YscU_{211-354,N263A} (pISO117). Elution of GST-tagged proteins was carried out with 2.5-10 mM glutathione. Washing and elution fractions were analyzed by immunoblot with anti-YscP and anti-YscU antibodies.

FRET

For a second attempt to investigate binding between YscP and YscU, the FRET (Fluorescence Resonance Energy Transfer) technology was used. Here, a donor chromophore in its electronic excited state, transfers energy to an acceptor chromophore (in proximity, typically less than 10 nm) through non-radiative dipole-dipole coupling. FRET is a widely used method for reporting the interaction of macromolecules [166, 167]. To use FRET there are three prerequisites: first, there must be an acceptor and a donor probe, second, the emission spectrum of the

donor must overlap with the absorption spectrum of the acceptor and third, the distance between donor and acceptor should be less than ~ 7 nm (Förster, 1948). Interactions between the soluble cytoplasmic domain of YscU (aa 211-354) and tail peptide of YscP (aa 497-515) were studied using Alexa Fluor 488 and Alexa Fluor 546 (Invitrogen) labelled proteins. These Alexa Fluor dyes selectively label proteins at cysteine residues. The cytoplasmic domain of YscU does not contain a cysteine residue, but a serine at position 351, close to the C-terminus (Figure A13 A) of the protein. The S351C mutation was tested *in vivo* to assure that this mutation does not interfere with the function of YscU. The *yscU*_{N263A,S351C} and *yscU*_{S351C} mutants were engineered by site-directed mutagenesis and cloned downstream of the pBAD promoter. YscU_{S351C} and YscU_{N263A,S351C} were expressed *in trans* in a Δ *yscU* strain to test these mutants for their ability to complement the knockout strain. The S351C mutation in YscU and YscU_{N263A} complement the Δ *yscU* strain to the same level as the corresponding controls (YscU and YscU_{N263A}, respectively; Figure A13B). As shown in Figure A13 B wt Yop secretion was detected by Coomassie-stained SDS-PAGE of the supernatant fractions for the YscU_{S351C} mutant. The secretion pattern for YscU_{N263A,S351C} was similar to the pattern observed for the cleavage site mutant YscU_{N263A} [130]. The export of YscP and LcrV were confirmed by immunoblotting using anti-YscP and anti-LcrV antibodies (Figure A13 B). Expression levels of YscU_{S351C} and YscU_{N263A,S351C} corresponded to the pattern observed for the controls (Figure A13 B). Therefore, the S351C mutation in YscU did not influence the function of YscU and can be used to label the cytoplasmic domain of YscU and YscU_{N263A}.

YscP harbours five cysteine residues. To assign a function to the YscP tail (described in a previous chapter), only the last 29 amino acids of YscP including one additional cysteine, introduced at the C-terminus, were used for the interaction studies with YscU. This additional cysteine at the C-terminus of YscP was tested *in vivo* not to influence the function of YscP. Therefore a cysteine was added to the C-terminus of the full-length YscP (Figure A13 A) using site-directed mutagenesis and the resulting gene was cloned downstream of a pBAD promoter. Yop secretion was analyzed by Coomassie-stained SDS-PAGE of the supernatant fractions for the YscP_{C516} mutant (Figure A13B). Export of YscP and LcrV was confirmed by immunoblotting with anti-

YscP and anti-LcrV antibodies (Figure A13 B). The expression level of YscP_{C516} corresponded to the pattern observed for its corresponding control (YscP wt, Figure A13 B). The obtained results showed that the C516 mutation in YscP did not influence the function of YscP and therefore can be used to label the C-terminal peptide of YscP.

YscU_{211-354,S351C} and YscU_{211-354,N263A,S351C} were cloned downstream of a T7 promoter as fusion to a GST-tag harbouring a PreScission protease cleavage site (pGEX-6P-1) and the resulting proteins were purified (data not shown).

First attempts were carried out to label the synthetic C-terminal peptide of YscP_{C516}. However, due to the small size of the peptide (30 aa) it was so far not possible to purify the labelled peptide from excess dye (data not shown).

The protocol for labelling and purification of the synthetic YscP_{C516} peptide and for the cytoplasmic domain of YscU_{S351C} and YscU_{N263A,S351C} need to be established in order to study interactions using FRET.

Figure A13

Cysteine mutations in the C-terminus of YscU, YscU_{N263A} and YscP do not influence needle length control.

A. Schematic representation of the cysteine substitution in YscU (pSTW63) or YscU_{N263A} (pSTW61) and the cysteine addition at the C-terminus of YscP (pSTW60).

B. Yops secreted by *Y. enterocolitica* E40 wt (pYV40), *Y. enterocolitica* E40 Δ yscP (pLJ4036), *Y. enterocolitica* E40 Δ yscP (pLJ4036) mutant bacteria over-expressing YscP (pLJ6) or YscP_{C516} (pSTW60) *in trans* from the pBAD promoter, *Y. enterocolitica* E40 Δ yscU (pLY4001), *Y. enterocolitica* E40 Δ yscU (pLY4001) mutant bacteria over-expressing YscU (pLY7), YscU_{S351C} (pSTW63) or YscU_{N263A,S351C} (pSTW61) *in trans* from the pBAD promoter. Supernatant fractions (SN) and total cell (TC) fractions of the same cultures were analyzed by immunoblot with anti-YscP, anti-LcrV and anti-YscU antibodies.

Overlays

To further identify other binding partners of YscP, interactions between YscP and proteins secreted by the type III secretion machinery were analyzed by an overlay assay. A construct encoding the full-length *yscP* fused to a N-terminal GST-tag was generated and expressed in *E. coli* (see previous chapter). The supernatant fractions of *Y. enterocolitica* wt, were separated by SDS-PAGE and transferred to a nitrocellulose membrane. The membranes were incubated with the purified full-length YscP and as control without protein. An interaction between the full-length YscP and two proteins secreted by the *Yersinia* injectisome was detected (Figure A14). The two bands observed corresponded to the sizes of YopB or YopD and YopH. Since YopH is a late substrate, the interaction with YscP is most likely unspecific. In contrast, YopB and YopD are intermediate substrates and interaction was confirmed by using the supernatant fraction of a $\Delta yopBD$ strain where the major band disappeared (Figure A14). This knockout strain, however, assembles wt needles suggesting that also this interaction is likely to be unspecific. Other interactions were not detected, which does not exclude interactions undetectable in this experimental setup.

Figure A14

Overlay assay to identify binding partners of YscP.

Proteins secreted by *Y. enterocolitica* E40 wt (pYV40), *Y. enterocolitica* E40 $\Delta yscP$ (pLJ4036) and *Y. enterocolitica* E40 $\Delta yopBD$ (pISO4005) mutant bacteria were separated by SDS-PAGE and transferred to a nitrocellulose membrane. The membranes were subsequently used for overlay assays with either purified YscP as probe or without protein (indicated on the left). After incubation with or without protein (control), bound YscP was analyzed by immunoblotting using anti-YscP antibodies.

Structure/purification

In order to obtain a crystal structure of parts of the YscP protein, several YscP constructs were engineered as GST-fusions (GST-YscP_{wt} (pSTW19), GST-YscP_{367-515t} (pSTW20), GST-YscP₄₉₇₋₅₁₅ (pSTW51), GST-YscP₁₋₁₃₇ (pSTW53)), which were analyzed by the group of Dirk Heinz at the Helmholtz Insitute in Braunschweig, Germany.

However, so far non of the constructs which were soluble were able to crystallize.

Does YscP measure needle length inside or outside the needle?

YscP is proposed to be a molecular ruler, measuring the needle length while being stretched during needle assembly ([53, 157], previous chapter). To address the question whether it is inside or outside of the growing needle, two YscP mutants were engineered with a thrombin cleavage site (Figure A15 A). In presence of thrombin protease in the culture supernatant, YscP should be cleaved when it is outside of the bacterium (Figure A15 B). Cleavage of YscP while measuring the growing needle would most likely result in extra-long needles, since YscP would not be able to sense the tip of the growing needle (Figure A15 B). In contrast, when YscP is itself inside the channel of the growing needle it would be protected from the protease and length measurement should not be impaired (Figure A15 B). However, since a certain extent of YscP remains non-cleaved at the early time-point (Figure A15 D) even upon changing various conditions, a conclusion could not be drawn from these experiments. The non-cleaved amount of YscP might control needle growth or YscP acts outside the growing needle but is not accessible for the protease. Another attempt to address the question whether YscP is outside or inside the needle channel while measuring needle length is using proteinase K. These experiments are described in the Master Thesis of Lisa Metzger.

The thrombin cleavage site was introduced either between the two export signals of YscP (pSTW1) or after the second export signal (pSTW2) by site-directed mutagenesis. As shown in Figure A15 C, both constructs were cleaved by thrombin protease after a normal *in vitro* secretion experiment (see Methods, the medium was supplemented with 25 U/mL thrombin protease at the shift to 37 °C).

Figure A15

Thrombin protease cleaves YscP_{ΩTCS} but does not influence needle length control.

A. Schematic representation of YscP harbouring the thrombin cleavage site (TCS) either between export signal 1 and 2 (pSTW1) or after the second export signal (pSTW2).

B. Schematic representation of possible scenarios. YscP is inside the growing needle channel and protected from cleavage (a), or outside and accessible for the protease (b)

C. Supernatant fractions (SN) and total cell (TC) fractions of *Y. enterocolitica* E40 wt (pYV40), *Y. enterocolitica* E40 Δ yscP (pLJ4036) and *Y. enterocolitica* E40 Δ yscP (pLJ4036) bacteria over-expressing YscP_{ΩTCS1} (pSTW1) or YscP_{ΩTCS2} (pSTW2) *in trans* from the pBAD promoter. Thrombin protease was added to the culture supernatant at the temperature shift to 37 °C. Supernatant (SN) and total cell (TC) fractions were analyzed by immunoblot using anti-YscP antibodies.

D. Supernatant (SN) fractions of the same cultures as in (C) and *Y. enterocolitica* E40 Δ yscP (pLJ4036) bacteria over-expressing YscP (pLJ6) *in trans* from the pBAD promoter. Samples were taken 90 min after induction of the type III secretion system. Supernatant (SN) fractions were analyzed by immunoblot using anti-YscP antibodies.

Methods

Bacterial strains

The different strains used in this study are listed in Table I.

Construction of plasmids

Bacterial strains, plasmids and genetic constructions are listed in Table II. *E. coli* Top10 (Invitrogen), *E. coli* GM48 [168] or *E. coli* BW19610 [169] were used for plasmid purification and cloning. Bacteria were routinely grown on Lysogeny Broth (LB) agar plates and in liquid LB medium. Ampicillin was used at a concentration of 200 µg/mL to select for expression vectors. Plasmids were generated using either Pfu turbo polymerase (Stratagene) or Vent DNA polymerase (New England Biolabs). The oligonucleotides used for genetic constructions are listed in Table III. All constructs were confirmed by sequencing using a 3100-Avant genetic analyzer (ABI Prism).

Induction of the *yop* regulon and Yop protein analysis

Bacteria were routinely grown on LB agar plates and in liquid brain-heart infusion (BHI; Remel) medium. For the induction of the *yop* regulon, *Y. enterocolitica* strains were inoculated to an O.D.₆₀₀ of 0.1 and cultivated in BHI medium supplemented with 35 µg/mL nalidixic acid, 4 mg/mL glucose, 20 mM MgCl₂ and 20 mM sodium oxalate (BHI-Ox) 2 h at RT, then shifted to 37 °C and incubated for 4 h.

Proteins from the supernatant were precipitated on ice for one hour with trichloroacetic acid 10% (w/v) final. Electrophoresis was carried out in 10%, 12%, or 15% (w/v) polyacrylamide gels in the presence of SDS (SDS-PAGE). Proteins secreted by 3.3×10^8 bacteria were loaded per lane. For detection of YscP in total cells by immunoblotting, 1.6×10^7 bacteria were loaded per lane. For YscP detection in supernatants by immunoblotting, the supernatants from 1.6×10^8 bacteria were loaded per lane. After electrophoresis, proteins were stained with Coomassie brilliant blue (Pierce) or transferred by electroblotting to a nitrocellulose membrane (Hybond-C extra (Pierce); 25 V; 30-45 min). The membranes were then blocked with 5% (w/v) non-fat dried milk in PBS-T (PBS, 0.2% (v/v) Tween) for 45 min or over night at 4 °C.

Immunoblotting was carried out using a polyclonal rabbit anti-YscP antibody (1:3000; MIPA57; purified). Detection of immunoblots was performed with a secondary swine anti-rabbit antibody conjugated to horseradish peroxidase (1:5000; Dako) before development with supersignal chemiluminescent substrate (Pierce) or Amersham ECL PlusTM Western Blotting Detection System (GE Healthcare).

Expression of the different *yscP* genes cloned downstream from the pBAD promoter was routinely induced by adding 0.2% arabinose to the culture just before the shift to 37 °C, and again 2 h later. Ampicillin was used at a concentration of 200 µg/mL to select for the expression plasmids and instead of glucose, glycerol was used as carbon source at a final concentration of 4 mg/mL.

Needle length measurement

Visualization of needle-like structures at the cell surface of the bacteria was done by transmission electron microscopy as described in references [26, 130].

Purification of His₆-YscP from inclusion bodies

His₆-YscP variants were expressed in *E. coli* BL21 (DE3) Rosetta. At an O.D.₆₀₀ of ~ 0.5, expression of recombinant N-terminal His-tagged *yscP* genes was induced by the addition of 0.2% L-arabinose. After 4 h of incubation at 37 °C, cells were harvested by centrifugation (3000 g / 4 °C / 10 min). The bacterial pellet was resuspended in 2 mL lysis buffer (10 mM Tris-HCl pH 8.0, 0.5 M NaCl, 1 mM PMSF, 5 mM DTT and 0.01% Nonidet P 40 substitute (Fluka, #74385; NP 40)). After sonication, the extract was treated with 5 U DNase I for 1 hour at 37 °C. Inclusion bodies (IB) were sedimented by centrifugation (18500 g / 30 min / 4 °C). Pelleted inclusion bodies were washed twice with wash buffer A (10 mM Tris-HCl pH 8.0, 0.5 M NaCl, 1 mM PMSF and 0.1% NP 40), followed by spinning at 18500 g for 30 min at 4 °C. The washed inclusion bodies were dissolved in 2 mL of IB lysis buffer (10 mM Tris-HCl pH 8.0, 100 mM NaH₂PO₄, 500 mM NaCl, 0.1% NP 40, 8 M urea) and left overnight at 4 °C. Insoluble material was removed by centrifugation at 18500 g for 10 min.

The supernatant from 100 mL bacterial culture was incubated with 1 mL nickel-sepharose beads for 2 h at 4 °C. The mixture was then poured on a BioRad column.

Bound proteins were washed with wash buffer B (2 x 10 mL: 10 mM Tris-HCl pH 8.0, 100 mM NaH₂PO₄, 500 mM NaCl, 0.1% NP 40, 8 M urea). To remove contaminants, the column was washed with an additional 20 mL of wash buffer supplemented with 10 mM imidazol. The His-tagged proteins were recovered from the column with elution buffer (5 x 1 mL: 10 mM Tris-HCl pH 8.0, 100 mM NaH₂PO₄, 500 mM NaCl, 0.01% NP 40, 250 mM imidazole and 8 M urea). Purity of the eluted protein fraction was analyzed by SDS-PAGE. Protein concentrations were determined using the Bradford-assay

Purification of GST-tagged proteins

GST-fusion proteins were expressed in *E. coli* BL21 (DE3) Rosetta. Bacteria were cultivated in 100-300 mL LB medium at 37 °C up to an O.D.₆₀₀ of 0.6. Then, expression of the fusion protein was induced by addition of 0.2 mM IPTG and the cultures were grown for 4 h at 37 °C. After harvesting the bacteria, the cell pellet was resuspended in 1/20 volume phosphate buffered saline (PBS) containing protease inhibitors (Complete Mini, Roche). Cells were lysed by sonication and unbroken cell debris was removed by centrifugation (15500 g / 30 min / 4 °C). The supernatant was incubated with 1/100 volume glutathione sepharose 4B (Amersham) (bed volume) for 2 h or overnight at 4 °C on a rotating wheel. The matrix was separated by centrifugation (500 g / 5 min / 4 °C) and washed three times with PBS containing protease inhibitors and once with cleavage buffer (50 mM Tris-HCl pH 7.5, 150 mM NaCl, 1 mM EDTA, 1mM DTT). GST-tagged proteins were eluted using PreScission protease (16 U/100 µL glutathione sepharose bed volume) in cleavage buffer for 3-5 h at 4 °C. Glutathione sepharose beads were washed twice with cleavage buffer to elute residual cleaved proteins. Purity of the eluted protein fraction was analyzed by SDS-PAGE. Protein concentrations were determined UV spectroscopy.

Overlay assay

Supernatant fractions of secreting bacteria were separated on a 15% SDS-PAGE, transferred to nitrocellulose membrane (Hybond-C extra; Pierce) and stained with Ponceau S solution to visualize the transferred proteins. The membranes were then blocked with 5% (w/v) non-fat dried milk in PBS-T (PBS, 0.2% (v/v) Tween) over night at 4 °C. After washing once with PBS-T, and once with binding buffer (PBS; 0.1% (w/

v) BSA; 0.1% (v/v) Tween), membranes were incubated 2 h at room temperature with or without purified YscP proteins in binding buffer (2 µg/mL protein final). The membranes were then washed for 1 h with PBS-T by changing the buffer several times. Bound YscP proteins were detected by immunoblotting using anti-YscP antibodies.

Purification of anti-YscP antibodies

The bacterial pellet of a 10 mL *Y. enterocolitica* Δ yscP overnight culture was resuspended in 3 mL PBS. Cells were lysed by sonication and proteins were precipitated by addition of 4 volumes acetone at 0 °C and incubation for 1 h on ice. Precipitated proteins were pelleted (10600 g / 10 min / 4 °C) and washed with 10 mL acetone. The protein pellet was dried overnight and was then incubated with 1 mL anti-YscP antibodies (MIPA57) for 30 min on ice. Purified antibodies were separated from the protein pellet by centrifugation (10600 g / 10 min / 4 °C) and the supernatant was stored at - 20 °C.

Retardation column

GST-tagged YscP proteins, YscP Δ tail proteins or GST alone were expressed in *E. coli* BL21 (DE3) Rosetta. Bacteria were cultivated in 100 mL LB medium at 37 °C up to an O.D.₆₀₀ of 0.6. Then, expression of the fusion protein was induced by addition of 0.2 mM IPTG and the cultures were grown for 4 h at 37 °C. After harvesting the bacteria, the cell pellet was resuspended in 1/20 volume phosphate buffered saline (PBS) containing protease inhibitors (Complete Mini, Roche). The cells were lysed by sonication and unbroken cell debris was removed by centrifugation (15500 g / 30 min / 4 °C). The supernatants were split into two samples with equal volume and incubated with either purified YscU₂₁₁₋₃₅₄ (from pISO116) or purified YscU_{211-354,N263A} (from pISO117) for 2 h at room temperature on a rotating wheel. Afterwards, the supernatant mix was incubated with 1/100 volume glutathione sepharose 4B (Amersham) (bed volume) for 2 h at room temperature on a rotating wheel. The mixture was then poured on a BioRad column. Bound proteins were washed with PBS (5 x 1 mL). The GST-tagged proteins were recovered from the column with 1 x 1 mL of 2.5 mM glutathione in PBS, 1 x 1 mL 5 mM glutathione in PBS, and 2 x 1 mL 10 mM glutathione in PBS. Proteins from the collected flow-through, washing and

elution fractions were precipitated on ice (1 h) with trichloroacetic acid 10% (w/v) final. Dried protein pellets were resuspended in 100 μ L SDS-sample buffer and analyzed by immunoblotting using anti-YscP and anti-YscU antibodies.

Acknowledgement

I am grateful to Prof. Dr. Guy R. Cornelis for his support, his trust in me, his ideas, our discussions, coffee-breaks and the open door.

I thank Prof. Dr. Urs Jenal and Prof. Dr. Christoph Dehio for being my PhD committee and the inspiring discussions during the committee meetings.

Lab members I want to thank all the past and present members of the Cornelis lab for the pleasant atmosphere, for coffee breaks and after work beers, for scientific discussions and mental support, for inspiring ruler models and BBQs. Special thanks to Lisa Metzger, Dr. Caroline Montagner, Dr. Francesco Renzi, Dr. Fabian M. Commichau, Pablo Manfredi, Dr. Manuela Mally, Andreas Diepold, Cecile Pfaff, Marina Kuhn, Cedric Cattin, Dr. Isabel Sorg, Dr. Hwain Shin, Dr. Michel Letzelter and Dr. Jaime Mota.

Collaborators I am grateful to Prof. Dr. Matteo Dal Peraro, Matteo Degiacomi and Dr. Marco Stenta from the EPF Lausanne for our fruitful collaboration and for giving me a completely different view on my project.

Biozentrum colleagues Thank you for the good atmosphere on the floor and for scientific support. Special thanks to Michaela Hanisch, Roger Sauder, Gianni Morson, Vesna Olivieri, Ursula Sauder, Roland Gut, Andreas Hefti and Loredana D'Anna.

My friends Thanks a lot for your infinite support, your friendship, your patience. Special thanks to Kerstin & Michel, Helo, Rainer, David, Caro, Tina, Emilio and Yücel.

Meine Familie Ein ganz besonderer Dank gilt meiner Familie, ohne die diese Arbeit nicht möglich gewesen wäre. Danke, dass ihr für mich da seit, mich unterstützt und an mich glaubt.

Alex "Happiness is only real when shared."- Into the wild.
Danke das Du an meiner Seite, und immer für mich da bist.

Curriculum vitae

Stefanie Wagner

Bungestrasse 18
4055 Basel
Switzerland
Phone: +41-(0)61-3215867
Email: stefanie.wagner@unibas.ch

Date of birth: October, 2nd 1979
Place of birth: Frankfurt/Höchst, Germany
Nationality: German
Marital status: Single

Education

10.1999 - 09.2001	Basic studies in biology, Darmstadt Technical University, Germany
10.2001 - 03.2004	Main studies in biology, Darmstadt Technical University, Germany
10.2004 – 12.2004	Oral diploma examinations
01.2005 – 09.2005	Diploma thesis with Prof. W. Keller, Biozentrum, University of Basel, Division of Cell Biology, Switzerland
09.2005	Graduation Degree: Diplom-Biologin
10.2005 – 12.2009	PhD thesis with Prof. Guy R. Cornelis Biozentrum, University of Basel, Basel, Infection Biology, Switzerland
Gap in the CV	03.2004 - 07.2004 Journey to Argentina, Chile, Bolivia, Peru, Brasil and the U.S.A.

Professional Experience

05.2002	Practical Traineeship with Priv.-Doz. Dr. A. Robitzki Fraunhofer Institute for Biomedical Engineering, St. Ingbert, Germany
10.2003 - 11.2003	Practical Training with Prof. H. U. Göringer Institute of Microbiology and Genetics, Darmstadt Technical University, Germany
12.2003 - 01.2004	Effect of mutations in <i>yscP</i> on type III secretion Practical training with Prof. G. Cornelis Biozentrum, University of Basel, Division of Molecular Microbiology, Switzerland
01.2005 – 09.2005	Genetic interactions between a new poly(A) polymerase complex and RNA processing factors in <i>S. cerevisiae</i> Diploma thesis with Prof. W. Keller Biozentrum, University of Basel, Division of Cell Biology, Switzerland
10.2005 – 12.2009	Length control of the <i>Yersinia</i> injectisome needle PhD thesis with Prof. Guy R. Cornelis

Biozentrum, University of Basel, Basel, Infection Biology, Switzerland

- 01.2010 – present Length control of the Salmonella injectisome needle
Post-Doc with Prof. Guy R. Cornelis
Biozentrum, University of Basel, Basel, Infection Biology, Switzerland
- 06.2007 FEBS/EMBO Advanced Lecture Course
Cellular and Molecular Biology of Membranes
Cargèse, Corsica, France

Teaching Experience

Assistant and supervisor of an experiment in the annual students Blockkurs: 1 week per year

Practical training with 3rd year students in Molecular Microbiology

Co-supervision of Project work: Cedric Cattin (09.2007 - 11.2007)

Evaluation of the AFM to test the hypothesis of a molecular ruler controlling bacterial injectisome needle length

Supervision of Master Thesis: Lisa Metzger (08.2008 - 10.2009)

The assembly of one injectisome needle involves only one molecule of YscP ruler
